40 mg trimethoprim and 200 mg sulfamethoxazole

Suspension B.I.D.

Acute
Otitis
Media

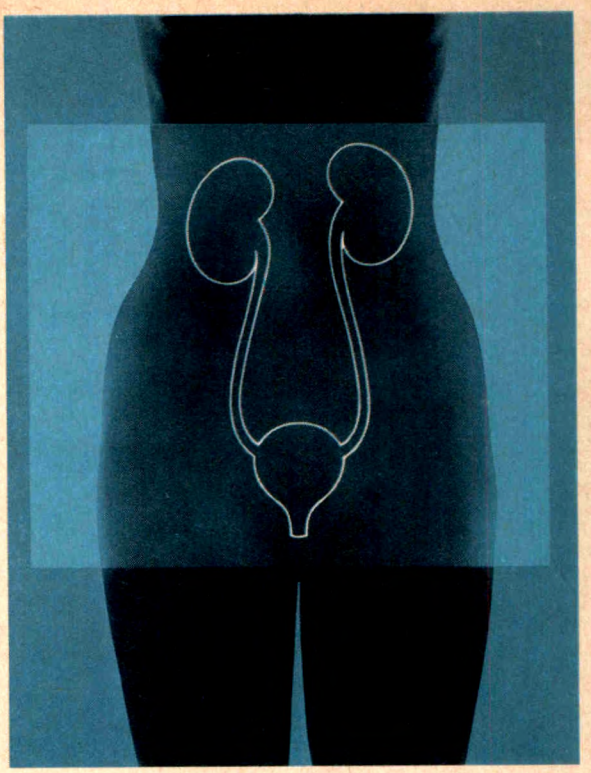
where the action is.

In acute otitis media

Septra Suspension provides effective antibacterial action against susceptible strains of H influenzae and S pneumoniae (D pneumoniae), the pathogens most likely to cause acute otitis media in children.

Septra Suspension is useful in many patients, but especially in those with penicillin allergy or with infections caused by ampicillin-resistant H influenzae. Limited clinical data are presently available on the effectiveness of treatment of acute otitis media with Septra when the infection is due to H influenzae resistant to ampicillin. However, in vitro data is highly favorable; when over 200 strains of ampicillin-resistant H influenzae were tested, all proved susceptible to TMP/SMX.*

And unlike most other antibacterials for the treatment of acute otitis media, Septra Suspension is administered on a convenient b.i.d. dosage schedule. The cherry-flavored suspension is well accepted by children.



In recurrent urinary tract infections

Septra Suspension provides effective antibacterial action in urine and blood against susceptible strains of E coli, Klebsiella-Enterobacter and Proteus. Whether the infection centers in the kidneys or bladder, Septra Suspension maintains effective levels at the site of the infection with just two doses a day.

Adequate fluid intake should be maintained and frequent urinalyses with careful microscopic examination performed during Septra therapy. Septra is contraindicated in infants under two months of age.

*In vitro data do not necessarily correlate with clinical results. Data on file, Burroughs Wellcome Co.
NOTE: Septra should not be used in the treatment of streptococcal pharyngitis.

Please see prescribing information on next page.

Burroughs Wellcome Co.
Research Triangle Park
North Carolina 27709

Septra® Suspension B.I.D.

Each teaspoonful (5 ml) contains: 40 mg trimethoprim and 200 mg sulfamethoxazole

Septra® DS B.I.D.

Each tablet contains: 160 mg trimethoprim and 800 mg sulfamethoxazole

Septra® DS Tablets Double Strength
Septra® Tablets
Septra® Suspension

INDICATIONS AND USAGE:

URINARY TRACT INFECTIONS: **For the treatment of urinary tract infections due to susceptible strains of the following organisms:** *Escherichia coli, Klebsiella-Enterobacter, Proteus mirabilis, Proteus vulgaris, Proteus morganii.* **It is recommended that initial episodes of uncomplicated urinary tract infections be treated with a single effective antibacterial agent rather than the combination.**

NOTE: Currently, the increasing frequency of resistant organisms is a limitation of the usefulness of all antibacterial agents, especially in the treatment of these urinary tract infections.

ACUTE OTITIS MEDIA: **For the treatment of acute otitis media in children due to susceptible strains of** *Haemophilus influenzae* **or** *Streptococcus pneumoniae* **when in the judgment of the physician Septra offers some advantage over the use of other antimicrobial agents. Limited clinical information is presently available on the effectiveness of treatment of otitis media with Septra when the infection is due to** *Haemophilus influenzae* **resistant to ampicillin. To date, there are limited data on the safety of repeated use of Septra in children under two years of age. Septra is not indicated for prophylactic or prolonged administration in otitis media at any age.**

SHIGELLOSIS: **For the treatment of enteritis caused by susceptible strains of** *Shigella flexneri* **and** *Shigella sonnei* **when antibacterial therapy is indicated.**

PNEUMOCYSTIS CARINII **PNEUMONITIS: For the treatment of documented** *Pneumocystis carinii* **pneumonitis. To date, this drug has been tested only in patients 9 months to 16 years of age who were immunosuppressed by cancer therapy.**

CONTRAINDICATIONS: Hypersensitivity to trimethoprim or sulfonamides. Pregnancy and during the nursing period. Infants less than two months of age.

WARNINGS: SEPTRA SHOULD NOT BE USED IN THE TREATMENT OF STREPTOCOCCAL PHARYNGITIS.

Clinical studies have documented that patients with Group A β-hemolytic streptococcal tonsillopharyngitis have a greater incidence of bacteriologic failure when treated with Septra than do those patients treated with penicillin as evidenced by failure to eradicate this organism from the tonsillopharyngeal area.

Deaths associated with administration of sulfonamides have been reported from hypersensitivity reactions, agranulocytosis, aplastic anemia and other blood dyscrasias. Experience with trimethoprim alone is much more limited, but occasional interference with hematopoiesis has been reported as well as an increased incidence of thrombopenia with purpura in elderly patients on certain diuretics, primarily thiazides.

Sore throat, fever, pallor, purpura or jaundice may be early signs of serious blood disorders. Frequent CBCs are recommended; therapy should be discontinued if a significant reduction in the count of any formed blood element is noted.

PRECAUTIONS: Use with caution in patients with impaired renal or hepatic function, possible folate deficiency, severe allergy or bronchial asthma. In glucose-6-phosphate dehydrogenase-deficient individuals, hemolysis may occur (frequently dose-related). During therapy, maintain adequate fluid intake and perform frequent urinalyses with careful microscopic examination and renal function tests, particularly where there is impaired renal function.

Since Septra may prolong prothrombin time in patients on warfarin, coagulation time should be reassessed when Septra is given.

ADVERSE REACTIONS: All major reactions to sulfonamides and trimethoprim are included, even if not reported with Septra. *Blood Dyscrasias:* Agranulocytosis, aplastic anemia, megaloblastic anemia, thrombopenia, leukopenia, hemolytic anemia, purpura, hypoprothrombinemia and methemoglobinemia. *Allergic Reactions:* Erythema multiforme, Stevens-Johnson syndrome, generalized skin eruptions, epidermal necrolysis, urticaria, serum sickness, pruritus, exfoliative dermatitis, anaphylactoid reactions, periorbital edema, conjunctival and scleral injection, photosensitization, arthralgia and allergic myocarditis. *Gastrointestinal Reactions:* Glossitis, stomatitis, nausea, emesis, abdominal pains, hepatitis, diarrhea and pancreatitis. *C.N.S. Reactions:* Headache, peripheral neuritis, mental depression, convulsions, ataxia, hallucinations, tinnitus, vertigo, insomnia, apathy, fatigue, muscle weakness and nervousness. *Miscellaneous Reactions:* Drug fever, chills, and toxic nephrosis with oliguria and anuria. Periarteritis nodosa and L. E. phenomenon have occurred.

Due to certain chemical similarities to some goitrogens, diuretics (acetazolamide and the thiazides) and oral hypoglycemic agents, sulfonamides have caused rare instances of goiter production, diuresis and hypoglycemia; cross-sensitivity may exist with these agents. In rats, long-term administration of sulfonamides has produced thyroid malignancies.

DOSAGE AND ADMINISTRATION: Not recommended for use in infants less than two months of age.

URINARY TRACT INFECTIONS AND SHIGELLOSIS IN ADULTS AND CHILDREN AND ACUTE OTITIS MEDIA IN CHILDREN:

Adults: The usual adult dosage for the treatment of urinary tract infections is two tablets or four teaspoonfuls (20 ml) every 12 hours for 10 to 14 days. An identical daily dosage is used for 5 days in the treatment of shigellosis.

Children: The recommended dose for children with urinary tract infections or acute otitis media is 8 mg/kg trimethoprim and 40 mg/kg sulfamethoxazole per 24 hours, given in two divided doses every 12 hours for 10 days. An identical daily dosage is used for 5 days in the treatment of shigellosis. The following table is a guideline for the attainment of this dosage using Septra Tablets or Suspension.

Children: Two months of age or older:

Weight		Dose—every 12 hours	
lb	kg	Teaspoonfuls	Tablets
22	10	1 (5 ml)	½
44	20	2 (10 ml)	1
66	30	3 (15 ml)	1½
88	40	4 (20 ml)	2 (or 1 DS tablet)

For patients with renal impairment:

Creatinine Clearance (ml/min)	Recommended Dosage Regimen
Above 30	Usual Standard Regimen
15-30	Half of the usual dosage regimen
Below 15	Use Not Recommended

PNEUMOCYSTIS CARINII **PNEUMONITIS:**
The recommended dosage for patients with documented *Pneumocystis carinii* pneumonitis is 20 mg/kg trimethoprim and 100 mg/kg sulfamethoxazole per 24 hours given in equally divided doses every 6 hours for 14 days. The following table is a guideline for the attainment of this dosage in children.

Weight		Dose—every 6 hours	
lb	kg	Teaspoonfuls	Tablets
18	8	1 (5 ml)	½
35	16	2 (10 ml)	1
53	24	3 (15 ml)	1½
70	32	4 (20 ml)	2 (or 1 DS tablet)

HOW SUPPLIED: TABLETS, containing 80 mg trimethoprim and 400 mg sulfamethoxazole—bottles of 40, 100, 500 and 1000 tablets; unit dose pack of 100.

ORAL SUSPENSION, containing the equivalent of 40 mg trimethoprim and 200 mg sulfamethoxazole in each teaspoonful (5 ml), cherry flavored—bottle of 450 ml. Also available in double strength, oval-shaped, pink, scored tablets containing 160 mg trimethoprim and 800 mg sulfamethoxazole—Compliance™ Pak of 20, bottle of 60 and unit dose pack of 100.

Letter From Abroad

The Fate of the Special Care Baby Unit

London.—I hope I may be forgiven if I seem to be a little cynical about the proliferating number of nonevents like Nannies' Sunday, National Breast Feeding Week, and the International Year of the Child. The calendar is crammed to capacity with birthdays, anniversaries, remembrance days, feast days, fast days, and holidays of obligation of one kind or another, all clamouring for the usual cards, flowers, and platitudes. It cannot be denied that they often provide a praiseworthy charitable outlet but they can also be used for commercial exploitation and even Breast Feeding Week had its spin-off with spates of paperbacks, conferences, television time, and an entirely new range of ladies' lingerie—in fact, all the usual publicity gimmicks with the exception, surprisingly, of a few free samples. True charity seems to find expression throughout the year without the artificial confines of a few days or weeks, the designation of which probably brings little extra benefit. As far as 1979 is concerned, it will always be inscribed in my memory as the year in which my own endeavours in neonatal intensive care, patiently built up over many years, were destroyed overnight and reached their lowest ebb.

On a fateful midsummer's day, our proverbial English weather unleashed a torrential downpour of rain that breached the frail defences of the little flat roof of the 15-year-old temporary hut housing our Special Care Baby Unit. Here, it is necessary to underline a fundamental difference between England and America where the vagaries of the weather appear to occasion neither surprise nor consternation. With us, unfortunately, it is well known that a half inch of snowfall is enough to paralyse the whole country, bringing chaos to roads, railways, telephones, water supplies, and a good many working activities not even remotely connected with ice or snow. It is simply a question of preparedness, like sweeping out gutters occasionally so that they are not overwhelmed by the first heavy shower of rain, causing enormous damage to electric fittings and costly equipment. Thus, our Special Care Baby Unit was hastily evacuated to a single room on our sick children's ward, an exodus worthy of Noah, complete with monitors, ventilators and faith. I, for one, believe implicitly that neonatal intensive care has enhanced the quantity and quality of its survivors.

The desperate search for a new home seemed at an end when we found a vacant space that might have been purpose-built for our needs. I imagine Brigham Young might have felt the same when he came upon the land of Salt Lake City. There were three empty nurseries with various side rooms in the very maternity hospital providing most of our referrals. The reasons for our separation from our obstetric colleagues go back into a long and convoluted history and the siting of a special care baby unit in a building in which no babies were ever born has long been a source of regret. We had evolved a transport system that was probably the first in the world and of which we were justifiably proud but often felt that if our Creator had intended obstetricians and paediatricians to work several miles apart, He would surely have furnished us with an umbilical cord longer than 35 cm.

We now had the nurses, the equipment, and the space. All that remained was the money to put in piped oxygen and to make a few minor alterations. It seemed little to ask but we are currently lurching through yet another financial crisis and the prospects of any contribution from the hospital budget stood at absolute zero. Then a leading children's charity—quick to grasp the immense benefit to mothers and babies—stepped in with a magnificent offer of nearly $100,000 to cover the cost. In the flush of success, thoughts gaily turned to the not far-off opening ceremony and which member of the Royal Family might agree to officiate. Little did we guess the problems ahead.

The first hurdle concerned the junior medical staff. Our junior doctors aim to work one night in three and no rearrangement of staff rotas would have made it possible to operate a special care baby unit in another building without at least one extra house-officer. After four months of wrangling, soul-searching, and sacrifice, this was eventually agreed. The next bombshell came in the form of an official missive to the effect that gifts to the National Health Service, the envy of the world, were not necessarily welcome no matter how well meant or munificent. It all depends on the "revenue consequences," the very thought of which strikes terror into the hearts of our administrators. The inevitable result is that it is now unbelievably difficult for generous people to give their money away to hospitals. Most donations have revenue consequences. Equipment needs bench space or floor space, it may have to be plugged in or, worse still, it may have to be serviced or repaired from time to time. Buildings need staff and staff need buildings. Even a fish tank needs an occasional change of water. We have just installed a computerized axial tomography head and body scanner, thanks to the grit and determination of a few stalwarts and to private donations amounting to nearly $1 million, and then only on the condition that all running costs would be found from private sources too.

After a somewhat ungracious acceptance of the offer for the new special care baby unit, the haggle began as to who was to do the work. Our Works Department was quick to dictate how it was to be done without wishing to do any of it. Since the disastrous reorganisation of the Health Service in 1974, the Works Departments are their own masters and do not take orders from hospital administrators. A project team was appointed and the project predictably came to a grinding halt. As more and more people became involved, the scheme became increasingly unrealistic and costly. Month after month went by, inflation eroding the original value of the donation until it became impossible to contain the cost within it. The most simple and menial task was costed at three or four times the amount we would spend in our own homes, and indeed ten times the cost of doing it ourselves. Offers of free paint, glass, and electric fittings were of no avail since painters and electricians were going to get their profits on these items whether we got them free or not. Add to this the subcontractors' profits, the main contractor's profit of another 15%, an inflation allowance, and a contingency allowance, and the scheme is soon priced out of existence.

So the chess game went on. Attack and defence, fortunes swaying, pieces

sacrificed, and the board slowly clears. Few pieces remain, a couple of white pawns, a bishop, and two knights against two black rooks and a superior number of black pawns. But with the end of the struggle in sight, a new threat has appeared.

The financial limitations of a welfare state must be plain to any responsible taxpayer. It all has to be paid for sooner or later and the noble concept of free health care cannot command a bottomless purse. This elementary truth is often lost on a vociferous minority that is least ready to lend its services for anything less than the going rate, let alone free. The writing has been on the wall for many years and this year's new government is committed to the electorate in bringing about a long overdue reduction in public spending. The big axe is beginning to fall and at last people are waking up to the realities of life. Our hospital has been told to spend $3 million less than last year. With inflation running at 10% to 15%, new wage awards, increased fuel costs, and expanding demands on most departments, the task would seem impossible. As yet, the axe has still to fall on the really basic cause of all our ills, overmanning. We have an entire tier of administration that could disappear overnight without any sense of loss. Wages and salaries are the largest item in the balance sheet but the slightest whisper of redundancies is enough to blow an industrial volcano, and so the axe is busily cutting patient services instead. A hospital here, a department there, a unit elsewhere. Our administrators—ironically the very tier we could so well do without—have drawn up a shopping list of proposed closures.

Heading this list is the closure of the Special Care Baby Unit. Second is the temporary closure of my colleague's Child Development Center. In just under two weeks, a group of worthy people will decide whether we can afford neonatal care for babies who will be born come what may. It is 15 months from the day that the rain came down and a year after we saw manna from heaven.

And so endeth the Year of the Child.

60 YEARS AGO IN THE AJDC

Prognosis in Operated Cases of Hypertrophic Stenosis of Pylorus

In a 4½ year period from Jan 1, 1915 to July 1, 1919, one hundred and sixty-three infants had a pyloromyotomy at the Babies' Hospital of New York. Of these 133 were males, 30 females. Duration of symptoms prior to operation ranged from one week or less (twenty cases) to over five weeks (twenty-nine cases). Of the total, 106 had been breast fed, 57 artificially fed. Weight loss prior to operation ranged from 10 to 20 per cent. (fifty cases) to over 30 per cent. (twelve cases).

The mortality of operated cases varied considerably dependent on a number of factors:

	Mortality, %
Total mortality 32/163	20
Sex	
Male	22
Female	10
Duration of symptoms	
less than 4 weeks	13
more than 4 weeks	35
Type of feeding	
Breast	11
Artificial	35
Weight at time of operation	
less than 7 pounds	28
greater or equal to 7 pounds	9
Percent of weight loss	
Breast fed 0 to 10 per cent.	0
10 to 20 per cent.	3
20 to 30 per cent.	28
Artificial 0 to 10 per cent.	0
10 to 20 per cent.	23
20 to 30 per cent.	45
more than 30 per cent	60

The authors observe: "It becomes evident that the operation per se is, perhaps, the least important factor in the mortality."—Alton Goldbloom, MD, Ralph C. Spence, MD, Babies' Hospital, New York (19:263, April 1920).

Books

Pediatric Trauma, edited by Robert J. Touloukian, 646 pp, with illus, $39.50, Somerset, NJ, John Wiley & Sons Inc, 1978.

This book is a welcome addition to the literature. It is one of the few collections addressed exclusively to pediatric trauma. The potential audience for the book is quite large because accidents are a common cause of morbidity in childhood and are the leading cause of mortality, and because good, comprehensive textbooks dealing with the subject are not already on everyone's shelf.

The book is divided into two sections and contains 20 chapters. Part 1 includes seven chapters grouped together under the heading "General Considerations"; part 2 considers specific injuries by organ system.

The "Table of Contents" is impressive for two reasons. First is the roster of authors. Second, the editor must be credited for thoroughness and thoughtfulness in his selection of topics. This is particularly evident in the general considerations section. There are the more or less expected chapters (overview of pediatric trauma, evaluation and initial management, and anesthesia and intensive care); in addition, there are chapters on the psychologic aspects of physical trauma, radiologic considerations, birth injury (written jointly by a surgeon and a neonatologist), and the battered child syndrome. Specific areas addressed in part 2 are injuries to soft tissues, brain and spinal cord, the eyes, the heart and thorax, vessels, the abdomen, the kidneys, the lower urinary tract and perineum, the skeleton, hands, and skin (burns).

The photographs are of exceptionally high quality and are plentiful. In the chapter on the injured hand, for example, more than half of the 45 pages (excluding the three-page bibliography) are given to the presentation of 57 photographs.

Pediatric Trauma is in no way a manual to provide instantly to physicians and surgeons the necessary competence to manage injured children. The chapters are long and comprehensive, with consideration of pathophysiology and history. It is a book to be used for reference, but the writing style of several chapters suggests that the authors intended them to be read as well as referred to. And, unlike the "major" pediatric and surgical texts, this volume is not unwieldy in size or weight.

The authors of various chapters lean heavily on the experience gained at their own institutions. This creates problems only in the first chapter (overview of pediatric trauma), in which diagrams are labeled with abbreviations that may not be understood by persons outside the Baltimore community; even in the first chapter, however, the personal references do not detract from the teaching messages, and, in most instances, they are helpful.

Pediatric Trauma is a multiauthored text that, like all such works, has problems and successes relating to the number of contributors. An obvious consideration is that persons who are considered experts in their particular field are able to concentrate on only their own area. On the other hand, complication and contradictions are a potential problem. In many places in this book, the hand of the editor is clearly evident, guiding the reader from one chapter to another, as is appropriate and appreciated. There are, however, lapses in the editing that result in confusion and, possibly, serious error. Most notable are recommendations for similar therapy given in one chapter on a dose-per-pound basis and in another chapter on a dose-per-kilogram basis; the reader should not be forced to make such adjustments (nor depended on to do so). Also, the recommendations are not necessarily consistent from one chapter to the next, reflecting (accurately) that many points in management of trauma are guided by personal preference. For example, the management of seizures complicating craniocerebral trauma is addressed in two parts of the book, in the chapter entitled "Evaluation and Initial Management," and in the chapter on craniocerebral trauma. One author proposes vigorous treatment with intravenous amobarbital sodium, with a dosage as high as 5 mg/lb. He notes that, in addition, phenytoin, 2 mg/lb intramuscularly, should be given immediately followed by 1 mL [sic] per pound every six hours. Phenobarbital should be avoided because of its depressive effect. The other author states that phenobarbital is a good choice and lists his reasons for selecting this drug. The initial dose he recommends is 2 mg/kg with a daily dose of 4 to 6 mg/kg. This author does concede that short-acting agents such as amobarbital sodium may be used to treat a convulsion that is in progress, but no dosage is given, and there is no cross-reference to the earlier recommendation that includes a dosage. In addition to the editing problems in this example, one may also question the content: phenytoin is poorly absorbed from intramuscular sites and the intramuscular route should not be considered a preferred means of administering this drug; the doses of phenytoin and phenobarbital recommended for initial administration are insufficient to achieve a therapeutic level, so several doses over a prolonged period would be required before a patient would optimally be protected against seizures.

To whom will this text be of value? "More and more," the editor states in the preface, "the properly trained pediatrician must assume the role of the 'team captain,' particularly during the most important early days of management, and be fully aware of how to work up and assess the injured child. Furthermore, many minor injuries, if appropriately treated by their primary physician, never require a surgeon." The chapters vary in the success with which they address the nonsurgeon, however. This may be why the editor chose to address initial management of injured children in a separate chapter near the front of the book. One may well disagree with the author of that chapter about certain specific recommendations, but the general approach presented is excellent and well worth the time for anyone (nurse, physician's assistant, medical student, house officer, physician regardless of specialty) who will participate in the management of an injured child. The discussion of burns is also divided into two chapters, separating initial management and special ongoing care, and giving full attention to both.

There is emphasis throughout the book on the ways in which pediatric trauma differs from adult trauma, ways in which the injuries differ, the host responses differ, the patterns of injury differ, the physician's approach should differ, management differs, etc. The book is therefore valuable for emergency room teams used to dealing with adult patients and who are called on from time to time to assist injured children; they would be wise to consult this volume before extrapolating from their experience with adults.

Pediatric Trauma is now *the* reference text on the subject and as such should be available for consultation by physicians and nonphysicians preparing to participate in the management of injured children. Emergency room staff, pediatric surgeons and their trainees, and selected pediatricians and surgeons will glean a deeper understanding of pathophysiology and, based on recommendations in the text, will be able to develop an approach to injured children. Persons in the surgical subspecialties who deal with injured children will also find this a valuable resource. One reminder, however: using this book is not easy; it does not offer a shortcut approach. It requires time, attention, and thoughtful evaluation—but, then, so does the injured child.

Pediatric Nutrition Handbook, edited by Donough O'Brien and G. B. Forbes, 472 pp, Evanston, Ill, American Academy of Pediatrics, 1979.

This comprehensive handbook is geared primarily to physicians involved in infant and child health care, in recognition that most medical schools and hospital teaching centers give insufficient attention to nutrition as an integral part of health care. There are 38 chapters, covering basic nutrition, assessment of nutritional status, nutritional needs and feeding of infants and young children, availability of community nutrition services and food assistance programs, and clinical applications. The last section covers a wide variety of common clinical problems, as well as some that are relatively rare. Finally, there are several chapters grouped as "Miscellaneous Topics." This section includes nutritional aspects of vegetarianism, health foods and fad diets, megavitamin therapy, nutrition and athletic performance, and food additives. Included also are chapters on infection, immune mechanisms, and the relationship between iron nutritional status and incidence of infection in infancy (which might just as well have been incorporated into the section on clinical applications).

Twenty-eight authors contributed to the handbook, and some sections are reprints of previous statements of the American Academy of Pediatrics (AAP) Committee on Nutrition. The style varies, as would be expected, but does not deter from the overall usefulness of the book. For the most part, greater attention is given to the problems most commonly encountered by pediatricians in practice. Less attention, rightly, is devoted to situations requiring the services of specialists.

There are any number of minor points with which one might take issue. As an example, the term "recommended dietary allowance" is used appropriately in the text, whereas "daily requirement" is used in a table (which, by the way, concisely summarizes useful information about the vitamins, thus saving needless pages of text). The interchangeable use of the terms "recommended dietary allowance" and "requirement" causes some gnashing of teeth among nutritionists (these terms are defined very differently by purists), but likely will not be noticed by most physicians. The only serious defect is the lack of an index, which would increase the usefulness of the book as a reference tool.

This book has been needed for a long time, and the AAP Committee on Nutrition should be applauded for providing this information in an easily available and readable form.

Atlas of Abdominal Ultrasonography in Children, by Gary F. Gates, 283 pp, 109 illus (263 sonographic), $27.50, New York, Churchill Livingstone, 1978.

This *Atlas of Abdominal Ultrasonography in Children* is an excellent compilation of representative examples of abdominal ultrasonic images of childhood diseases. The atlas is organized into six chapters, with 109 figures composed of approximately 263 sonographic, 58 radionuclide scintiscan, 30 radiographic, and eight clinical and pathologic photographic pictures. The radiodiagnostic methods (scintigraphy and radiography) were corroborative and complimentary to ultrasonography. The quality of the sonograms, scintiscans, radiographs, and photographs is excellent. The sonograms are presented as black echos on a white background, hard-copy format.

Ultrasound is especially useful in pediatrics because it does not use ionizing radiation and because of its exopenetrant ("noninvasive") nature. The author uses the term noninvasive, which has been widely applied to ultrasound techniques despite the fact that sound waves are invasive or penetrant of tissues although apparently not injurious to them. To be effective in producing images, the sound waves must penetrate or invade tissues. This reviewer is suggesting "exopenetrant" as an alternative and possibly better term to more accurately convey the function of ultrasound. "Noninvasive," although a misnomer, is widely used and unfortunately has gained wide acceptance. "Invasive" imaging methods (use of guided catheters for angiography, use of radionuclides internally, etc) might be referred to as "endopenetrant" methods. The author emphasizes the ability of gray scale ultrasonography to demonstrate "normal or morbid anatomy" without dependence on organ function.

In chapter 1, general remarks include comparisons of ultrasound with other diagnostic methods, advantages of ultrasonography, and its limitations. A brief review is given of the various modes of sonographic scanning and general diagnostic criteria for cystic vs solid lesions. The problem of motion by the patient during sonography, the resultant needs for immobilization and occasional sedation are addressed. Proper attitudes for relating to children and their parents are emphasized in conjunction with specific scanning techniques in working with children.

Chapters 2 through 6 are concerned with specific abdominal organs or locations. Ninety-four relevant references through 1977 are offered, specific to each chapter. All of the 109 figures are accompanied by legends that contain abbreviated clinical in-

formation. In general, the author is successful in his purpose for writing the book and preparing this atlas although "Clinical Implications" might have been better offered in a more organized format within the text.

Overall, this atlas is a relevant source book regarding pediatric abdominal ultrasound. It should be useful for radiologists and ultrasonographers involved in the application of this relatively new and important diagnostic method to childhood abdominal diseases.

Corporal Punishment in American Education, edited by Irwin A. Hyman and James H. Wise, 471 pp, $25, Philadelphia, Temple University Press, 1979.

In 1977, two youths severely beaten by their junior high school principal brought before the US Supreme Court the controversial issue of corporal punishment. The resulting Ingram vs Wright decision sparked a furor in American education. The highest court of the land ruled that corporal punishment as a disciplinary tool does not violate the Eighth Amendment prohibition of cruel and unusual punishment. Two years after the Supreme Court ruling, Irwin Hyman and James Wise, in their compendium *Corporal Punishment in American Education,* have attempted to sift through the complex, multidisciplinary array of questions corporal punishment raises. However, as they state in their foreword, theirs is no dispassionate examination of the issue; it is a statement of the need for and search for rational alternatives, which is meant to inform the discussion in light of the Supreme Court ruling. The book is organized into eight sections, including historical perspectives, legal perspectives, causes and consequences, case studies, surveys and opinions, research, and alternatives. The articles range from polemical to informative, with most being somewhere between.

The book's strengths stem from the editors' selection of a wide variety of sources to make their case. There are, after all, no hard data explicitly concerned with corporal punishment; and as we draw and extrapolate from related research, such as laboratory studies on the effects of punishment and aggression and discussions of child abuse and juvenile delinquency, we begin to appreciate the complexity of the issue. Although some of the articles considered in isolation are weak, as a collection they make a compelling argument. Thus, Williams' historical essay documenting that corporal punishment has always been woven into the fabric of American society is substantiated by Reardon and Reynolds' Pennsylvania attitude survey that indicates strong present-day acceptance of the use of corporal punishment. More provocative but methodologically troublesome is Bellak and Antell's cross-cultural data suggesting a link between societies that condone corporal punishment in their schools and levels of aggression found in children's free play.

Research on the effects of punishment is also reviewed. Bongiovanni suggests that punishment works in the short-term—it does lead to the cessation of behavior. In fact, considering only the short-term, Wise remarks that punishment may be more effective than reward. However, its long-term effects are pernicious: corporal punishment perpetuates itself in a variety of violent behaviors. Other research cited suggests relationships between corporal punishment and juvenile delinquency, child abuse, and aggression. But at the crux of the issue and not recognized by the editors is that corporal punishment is a moral issue as well as an empirical question of effectiveness. Even if research were to prove corporal punishment an efficacious means of behavior control, I would still object to its use, since it violates the dignity of the individual and instructs impressionable children that force is an acceptable means of problem-solving.

Given the editors' stated goals, it is a shame that the book devotes so much space to convincing the reader of the evils of corporal punishment and so little space to alternatives. The reader who wades through the volume in sympathy with its basic premises will be disappointed by the small number of solutions this collection provides. The section on alternatives embodies many of the flaws of the book: unfortunately, there are too few concrete suggestions and thoughtful proposals. Although the book's intent is to counterbalance the effect of the Supreme Court's decision by proposing alternatives to physical punishment, these last few essays do not fulfill the book's promise.

For those deeply concerned with the issue of corporal punishment, this book provides a good introduction to the issue and raises provocative questions about relationships between corporal punishment and violence. However, a practitioner will not glean much practical knowledge from its pages.

Pediatric Hematology-Oncology, by Philip Lanzkowski, 432 pp, New York, McGraw-Hill Book Co, 1979.

Dr Lanzkowski calls his new textbook of hematology-oncology "a treatise for the clinician," and it seems to fit this description well. The book is not presented as an encyclopedic text of pediatric hematology-oncology. Rather, it presents a practical clinical approach to the differential diagnosis of hematologic disorders. The book was written to appeal particularly to the medical student, to the student of pediatric hematology-oncology, and to physicians practicing clinical pediatrics. It is easy to read and well indexed, and it includes a large number of tables. In this regard, Dr Lanzkowski has gone to great lengths to tabulate and summarize large blocks of data for concise presentation. This type of presentation is a great aid to the busy clinician or haggard house officer who lacks the time or inclination to read extensive discussions in the text.

The first ten chapters include disorders of RBCs, WBCs, and platelets. There is an additional chapter about blood coagulation and a final chapter on pediatric oncology. The oncology chapter constitutes about 25% of the total volume of this book.

The text, although readable, is not as well organized as the tabular material. This seems more related to the typesetting than to the structure of the presentation. For example, in the chapter regarding anemia in the neonatal period, the subheadings for hemorrhage, hemolysis, and failure of RBC production are inconsistent in format. Further, other headings and subheadings are difficult to follow in this and other chapters and diminish

the ease of locating material.

One of the strengths of the book is the chapter about iron deficiency anemia. Dr Lanzkowski has compiled a comprehensive review of iron metabolism. Tables are devoted to the etiology, the systemic effects, and the differential diagnosis of iron deficiency. Appropriate emphasis is given to those disorders wherein iron is lost through bleeding as well as those where intake of iron is deficient. Clinicians should find this chapter useful.

In the chapter regarding hemolytic anemia, the author has tabulated the etiology of hemolysis in a classical way into those causes external and those intrinsic to the RBC. Again, the tables and diagrams are useful for investigating hemolytic problems. I would criticize only that many of the tests presented for the diagnosis of hemolysis are neither necessary nor commonly ordered. For example, fecal urobilinogen, carbon monoxide, hemopexin, methemalbumin, and even RBC survival are usually unnecessary in the evaluation of a hemolytic anemia. It would have been helpful to the practitioner to designate those tests that are most useful in differential diagnosis.

As in any singly authored book, there is a strong reflection of the author's opinions. For example, not all pediatric hematologists would agree with Dr Lanzkowski's recommendation for daily penicillin prophylaxis in all patients with sickle cell anemia. Such prophylaxis would be more appropriate for those patients with sickle cell who have defective pneumococcal opsonization, a problem that is not discussed. In addition, the risk of drug-induced G6PD hemolysis in sickle cell anemia is overemphasized since patients with sickle cell have a young RBC population that is relatively resistant to oxidant damage.

About 25% of the book is devoted to pediatric oncology and provides an overview of the malignant disorders of childhood. The tables and charts are particularly useful. Dr Lanzkowski has tabulated the conditions associated with a high incidence of malignancy, the prognostic factors in malignant disorders, and the toxicities of the commonly used chemotherapeutic agents.

In summary, Dr Lanzkowski has done a fine job of gathering, consolidating, and presenting hematologic information for the student and the practitioner. His book is one of the most convenient sources for hematologic information.

Diagnosis of Viral Infections: The Role of the Clinical Laboratory, edited by David A. Lennette, Steven Specter, and Kenneth D. Thompson, 254 pp, Baltimore, University Park Press, 1979.

This little volume is a smorgasbord, with something for everyone's intellect to nibble on! It is a compilation of papers presented at a symposium entitled "Diagnosis of Viral Infections: The Role of the Clinical Laboratory," held in Philadelphia, Nov 9 to 10, 1978.

The practical role of the diagnostic virology laboratory is outlined at the outset in three separate chapters devoted to the hospital laboratory, the state laboratory, and the federal reference laboratory. The final chapter, "An Infectious Disease Viewpoint of Diagnostic Virology," is a companion piece to the introductory material. These chapters are particularly well written and extremely practical for pediatricians, as well as for laboratory scientists. Tables are provided that show the proportion of positive viral isolations from all clinical material. Results from Rochester, NY, Seattle, and Tucson, Ariz, indicate that it is possible to find a specific viral cause in 20% to 40% of the cases studied.

Not only can a high percent of cases be diagnosed, but results can be obtained rapidly. Dr Menegus writes that in Rochester, at least half of 480 viral cultures showed positive results by the seventh day and frequently as early as the first or second day. Dr Ray states that for the period 1976 to 1978, 71% of the preliminary reports were sent to the physician by the fifth day. Although diagnostic virology may, in the words of Dr Gershon, be like "a rebellious teenager" (not quite grown up), the practical services virology can provide for primary care physicians are delineated clearly.

The chapter by Dr Tom Smith on collection and transport of specimens is very timely. How to collect and send samples are the most frequent queries that I, as director of a clinical virology laboratory, am asked.

There are three clinically oriented chapters toward the end of the book, which contain a thorough discussion of acute viral CNS infections, a brief overview of congenital and neonatal infections, and a useful classification of viral respiratory syndromes.

The midportion of the book is devoted to particular laboratory techniques. I found the chapter entitled "The Role of Electron Microscopy in Diagnostic Virology" informative and refreshingly honest. Although written from the point of view of an experienced electron microscopist, the author was quick to point out that electron microscopy was not always the most apt technique. In other chapters, newer techniques of great promise, such as cell-mediated assays for specific viruses, enzyme-linked immunospecific assay (ELISA), and immune adherence hemagglutination were covered nicely.

As with all multiauthor volumes, the quality is uneven. Several chapters are mere forums in which authors present their preliminary research findings, which is neither pertinent for readers with a clinical background nor scientifically satisfying. Fortunately, the majority of the chapters are above reproach.

In conclusion, this book is excellent for laboratory physicians and scientists interested in establishing or improving diagnostic virology laboratories. Pediatricians with special interest in infectious disease would find the book a valuable addition to their professional library. Because the clinical chapters are particularly useful as a review of specific viral syndromes, and "how to use the virus laboratory" sections most practical, this book is a worthwhile reference for every hospital library.

Clinical Management of Mother and Newborn, by Gertie F. Marx, 274 pp, $29.80, New York, Springer Verlag, 1979.

Gertie F. Marx, MD, an anesthesiologist at the Albert Einstein College of Medicine, has elicited the aid of 11 anesthesiologists, five pediatricians, three obstetricians, and one statistician, 18 specialists in all, in writing a

scholarly book devoted to the first days after birth. Good writing with an almost uniformly clear style shows that the authors, most of whom are from the New York City area, were chosen wisely.

The bulk of the book, including ten of the 15 chapters, is an update and review of neonatal physiology, pathology, and treatment. An outstanding example of the latter is a chapter by Ermelando V. Cosmi, Professor of Anesthesiology and of Obstetrics, University of Rome, on "Exchange Transfusion of the Newborn Infant." This chapter, with 128 references, is the first extensive writing on this subject that I have encountered by a specialist outside the field of pediatrics. The first three chapters in the book are concerned with "Maternal Postpartum Problems." There is a chapter entitled, "The Normal Parent-Newborn Relationship," which includes currently fashionable practices, such as bonding. A final chapter is concerned with "Maternal and Perinatal Mortality," in which figures from New York City are given. Although comparable data of such extensive proportions would be difficult to obtain on a national scale, this should have been attempted.

On reading the chapters concerned with neonatal physiology one is again struck with the fact that the early work of numerous worthy neonatologists is frequently ignored by many modern authors. Although it is true that recent references are most likely to be available when current papers merely confirm the work of such pioneers as Barcroft, Dawes, and Smith, it is regrettable that their work is not recognized, especially in books where references are not restricted.

This book should be available in medical libraries and it will be valuable to students and practitioners. It is nicely printed, with many tables and line drawings, and a few photographs. In relation to most medical books, its size is small, and even by today's standards its price is outrageous.

HUGH A. CARITHERS, MD

Jacksonville, FL 32204

Books in Brief

Human Milk in the Modern World, by Derrick B. Jelliffe and E. F. Patrice Jelliffe (500 pp, New York, Oxford University Press Inc, 1978) (price not stated). This book is a rich compendium of data on breast-feeding and the virtues of human milk for the feeding of infants both in Western society and in the countries of the third world. It provides plenty of arguments for those who want to promote breast-feeding, and it includes an abundance of practical information that should be of great help to nursing mothers and their physicians. Every conceivable argument in favor of breast-feeding, lactation amenorrhea, mother-infant bonding, antiinfective properties, economies, antiallergic properties, enhancement of iron absorption, lower incidence of neonatal hypocalcemia, etc, is discussed in considerable detail. Methods of promoting breast-feeding are presented.

The biochemical aspects of human milk are presented in somewhat less detail than one would have expected from a book of this size, and there is no discussion of the inadequacies of human milk for tiny premature infants (see Fomon, Ziegler, and Vasquez, this JOURNAL 131:463-469, 1977; Committee on Nutrition, American Academy of Pediatrics, *Pediatrics* 62:826-834, 1978). However, the main thrust of this book is the social and cultural aspects of breast-feeding, and the authors make a strong plea for an increase in this practice worldwide.

Growth and Development of Children, ed 7, by George H. Lowrey (464 pp, Chicago, Year Book Medical Publishers, 1978) (paperback, price not stated). The seventh edition of this well-known work attempts to present an overview of human growth and development in all of its aspects. New or greatly expanded material in this edition deals with placental development, prematurely born infants, maternal-child relationships, cognitive development, immunological and endocrinological phenomena, facial growth, and nutritional influences. It presents a balanced view of this aspect of biology, which is the hallmark of pediatrics.

Human Body Growth in the First Ten Years of Life, by Howard V. Meredith (141 pp, $4 [paperback], Columbia, SC, The State Printing Co, 1978). This brief work presents data on physical growth values for infants and children from various countries around the world. Data on dentition and on certain body proportions are also included. The main emphasis is the presentation of the data themselves and the comparisons of infants and children of various cultural and geographic origins. Lists of references are provided for readers who want more detail; however, they will have to look elsewhere for information on the processes that underlie the phenomenon of growth.

Secular Trends in Human Growth, Maturation, and Development, edited by Alex F. Roche. Monographs of the Society for Research in Child Development, serial No. 179, vol 44 (120 pp, $7 [paperback], Chicago, University of Chicago Press, 1979). Today's children are taller and heavier than their peers of yesteryear, and these so-called secular changes have been documented in many countries around the world and have involved all social classes. The articles in this monograph review these data, and they remind us that certain features of maturation, particularly menarche, are now occurring at an earlier age. Today's children also seem to be a bit stronger; thus, it should come as no surprise that Olympic records have steadily improved through the years.

Paediatrics and Growth, edited by Donald Barltrop (157 pp, London, Fellowship of Postgraduate Medicine, 1978) (price not stated). This book consists of articles read at the Fifth Unigate Workshop, held at the Royal College of Physicians in May of 1977, and it includes verbatim discussion by the participants. Here one will find an up-to-date discussion of the various factors and phenomena that are responsible for the growth process, including embryonic and fetal as well as postnatal growth. The role of somatomedin (a polypeptide that is growth-hormone dependent) is presented, and there is an interesting discussion of the role of the fetal brain in stimulating intrauterine growth. There are chapters on growth disorders. The presentations and discussions are at a high level, and fundamental concepts are emphasized. This little book should be of interest to all students of human growth.

Ilosone® (erythromycin estolate)

WARNING

Hepatic dysfunction with or without jaundice has occurred, chiefly in adults, in association with erythromycin estolate administration. It may be accompanied by malaise, nausea, vomiting, abdominal colic, and fever. In some instances, severe abdominal pain may simulate an abdominal surgical emergency.

If the above findings occur, discontinue Ilosone promptly.

Ilosone is contraindicated for patients with a known history of sensitivity to this drug and for those with preexisting liver disease.

Indications: *Streptococcus pyogenes* (Group A Beta-Hemolytic) – Upper and lower respiratory tract, skin, and soft-tissue infections of mild to moderate severity.

Injectable penicillin G benzathine is considered by the American Heart Association to be the drug of choice in the treatment and prevention of streptococcal pharyngitis and in long-term prophylaxis of rheumatic fever.

When oral medication is preferred for treating the above-mentioned conditions, penicillin G or V or erythromycin is the alternate drug of choice.

The importance of the patient's strict adherence to the prescribed dosage regimen must be stressed when oral medication is given. A therapeutic dose should be administered for at least ten days.

Alpha-Hemolytic Streptococci (Viridans Group) – Short-term prophylaxis against bacterial endocarditis prior to dental or other operative procedures in patients with a history of rheumatic fever or congenital heart disease who are hypersensitive to penicillin. (Erythromycin is not suitable prior to genitourinary surgery when the organisms likely to lead to bacteremia are gram-negative bacilli or belong to the enterococcus group of streptococci.)

Staphylococcus aureus – Acute infections of skin and soft tissue which are mild to moderately severe. Resistance may develop during treatment.

S. (Diplococcus) pneumoniae – Infections of the upper respiratory tract (e.g., otitis media, pharyngitis) and lower respiratory tract (e.g., pneumonia) of mild to moderate severity.

Mycoplasma pneumoniae (Eaton Agent, PPLO) – Respiratory tract infections due to this organism.

Haemophilus influenzae – May be used concomitantly with adequate doses of sulfonamides for upper respiratory tract infections of mild to moderate severity. Not all strains of this organism are susceptible at the erythromycin concentrations ordinarily achieved.

Treponema pallidum – As an alternate treatment in penicillin-allergic patients. In primary syphilis, spinal-fluid examinations should be done before treatment and as part of follow-up after therapy.

Corynebacterium diphtheriae – As an adjunct to antitoxin, to prevent establishment of carriers, and to eradicate the organism in carriers.

C. minutissimum – In the treatment of erythrasma.

Entamoeba histolytica – For intestinal amebiasis only. Extraenteric amebiasis requires treatment with other agents.

Listeria monocytogenes – Infections due to this organism.

Legionnaires' Disease – Although no controlled clinical efficacy studies have been conducted, in vitro and limited preliminary clinical data suggest that erythromycin may be effective in treating Legionnaires' disease.

Contraindication: Known hypersensitivity to this antibiotic.

Warnings: (*See* Warning box above.) The administration of erythromycin estolate has been associated with the infrequent occurrence of cholestatic hepatitis. Laboratory findings have been characterized by abnormal hepatic function test values, peripheral eosinophilia, and leukocytosis. Symptoms may include malaise, nausea, vomiting, abdominal cramps, and fever. Jaundice may or may not be present. In some instances, severe abdominal pain may simulate the pain of biliary colic, pancreatitis, perforated ulcer, or an acute abdominal surgical problem. In other instances, clinical symptoms and results of liver function tests have resembled findings in extrahepatic obstructive jaundice.

Initial symptoms have developed in some cases after a few days of treatment but generally have followed one or two weeks of continuous therapy. Symptoms reappear promptly, usually within 48 hours after the drug is readministered to sensitive patients. The syndrome seems to result from a form of sensitization, occurs chiefly in adults, and has been reversible when medication is discontinued.

Usage in Pregnancy – Safety of this drug for use during pregnancy has not been established.

Precautions: Caution should be exercised in administering the antibiotic to patients with impaired hepatic function.

Recent studies of erythromycin reveal that its use in patients receiving high doses of theophylline may be associated with an increase in serum theophylline levels and potential theophylline toxicity. In such a case, the dose of theophylline should be reduced while the patient is receiving concomitant erythromycin therapy.

Surgical procedures should be performed when indicated.

Adverse Reactions: The most frequent side effects are gastrointestinal (e.g., abdominal cramping and discomfort) and are dose related. Nausea, vomiting, and diarrhea occur infrequently with usual oral doses.

During prolonged or repeated therapy, overgrowth of nonsusceptible bacteria or fungi is possible. If such infections arise, the drug should be discontinued and appropriate therapy instituted.

Mild allergic reactions, such as urticaria and other skin rashes, have occurred. Serious allergic reactions, including anaphylaxis, have been reported. (013079)

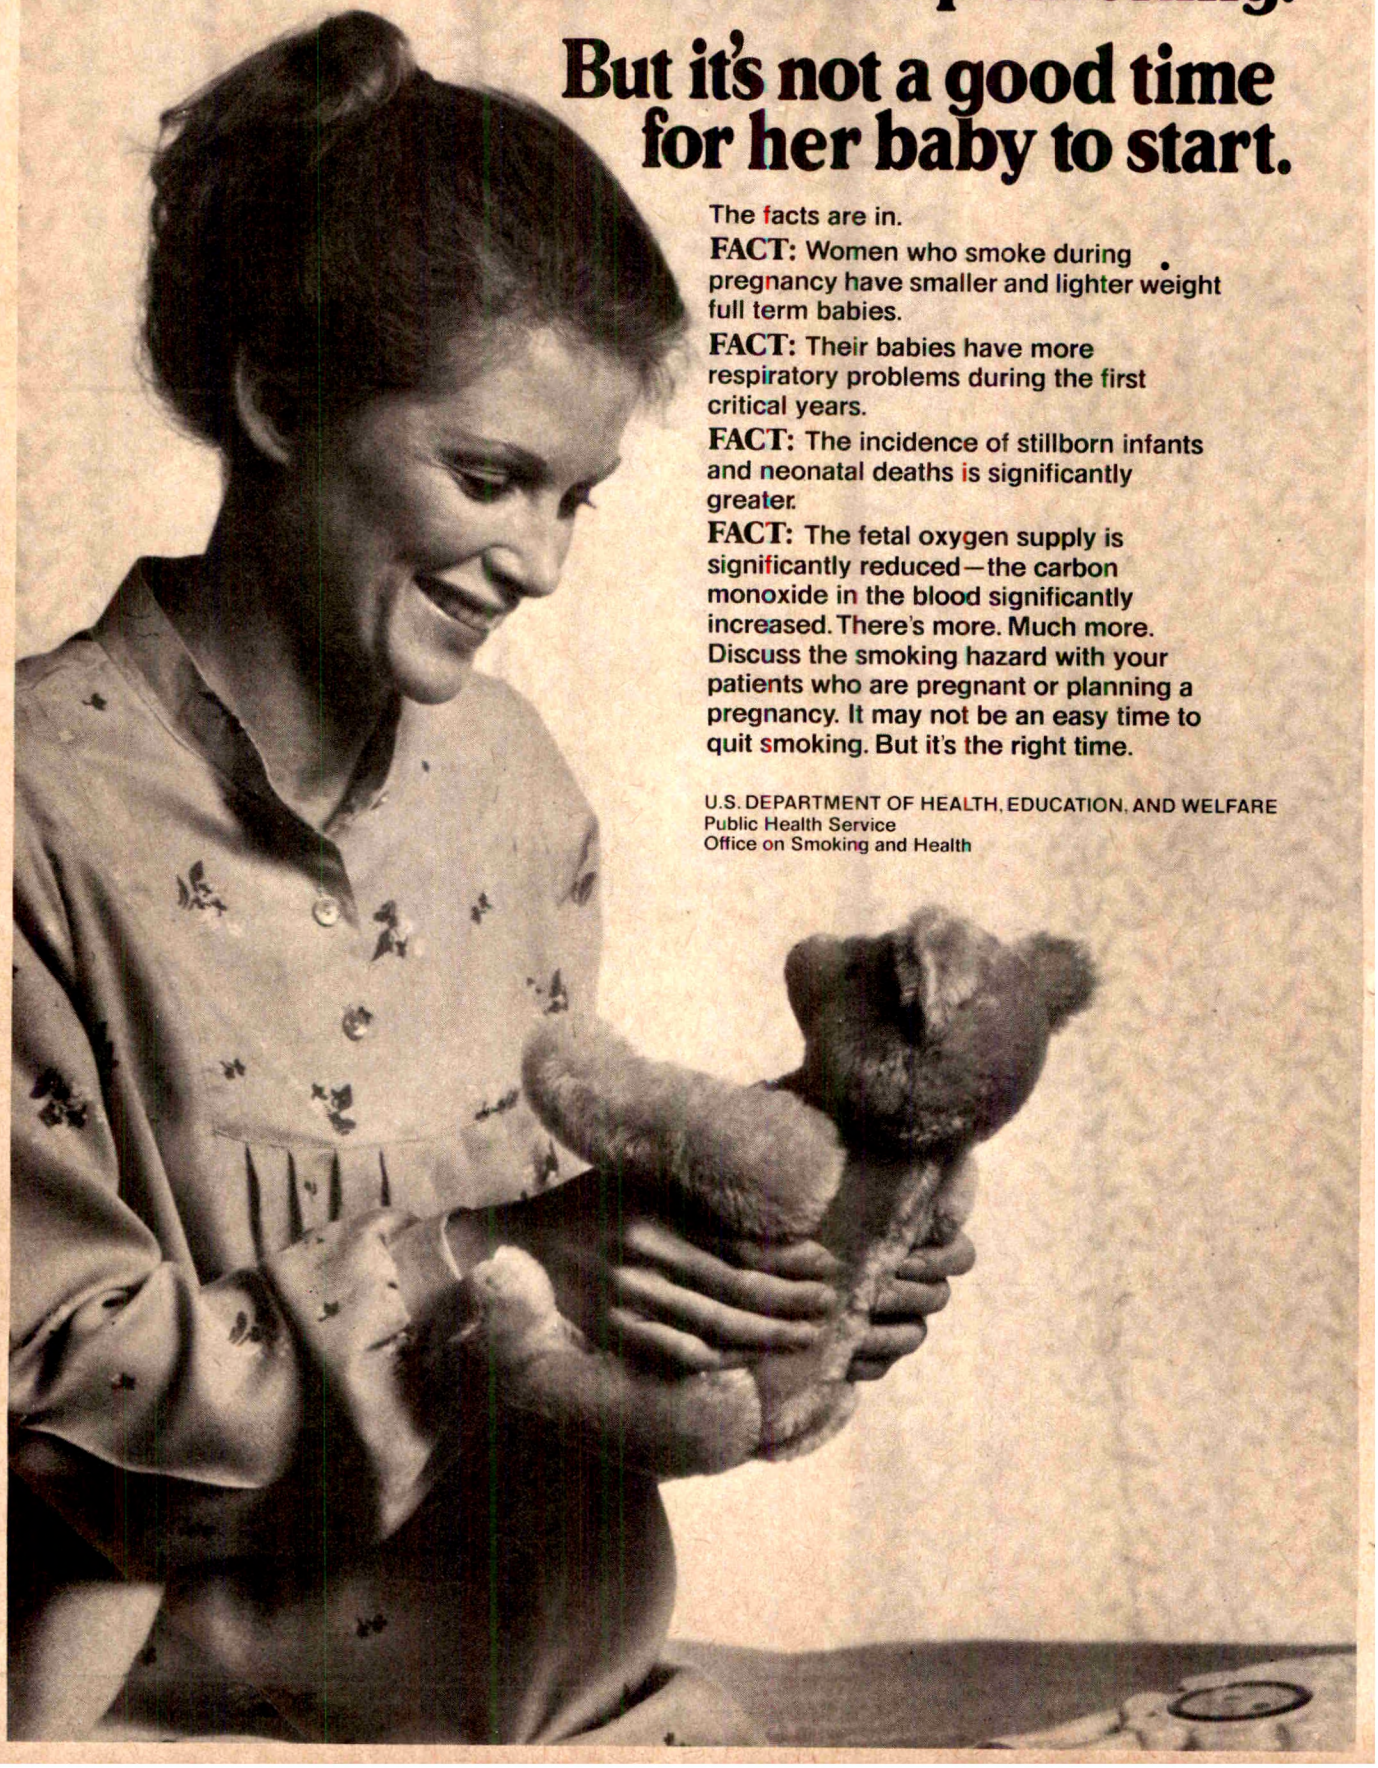
See adjoining column for summary of prescribing information.

This is not an easy time for her to stop smoking.

But it's not a good time for her baby to start.



The facts are in.

FACT: Women who smoke during pregnancy have smaller and lighter weight full term babies.

FACT: Their babies have more respiratory problems during the first critical years.

FACT: The incidence of stillborn infants and neonatal deaths is significantly greater.

FACT: The fetal oxygen supply is significantly reduced—the carbon monoxide in the blood significantly increased. There's more. Much more. Discuss the smoking hazard with your patients who are pregnant or planning a pregnancy. It may not be an easy time to quit smoking. But it's the right time.

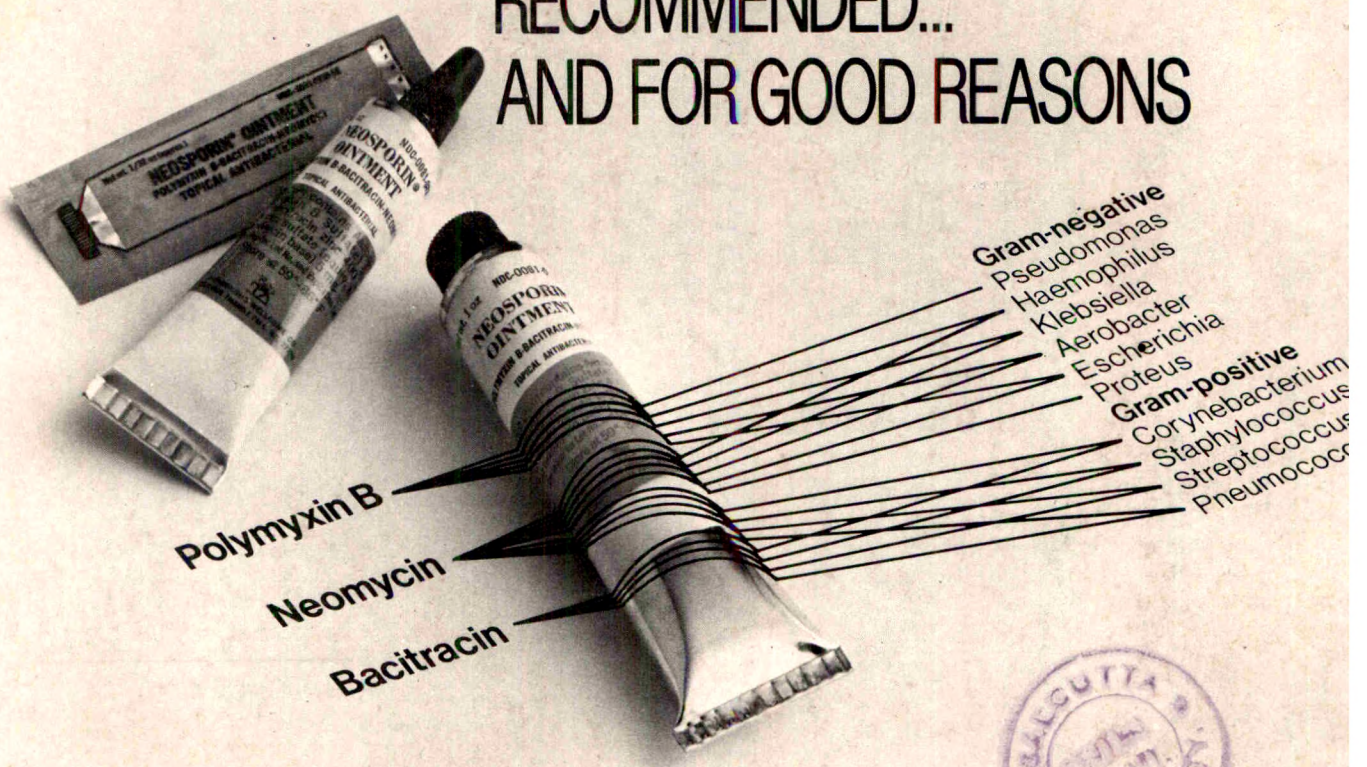
ONE HUNDRED YEARS WELLCOME

Burroughs Wellcome Co.
Research Triangle Park
North Carolina 27709

IT'S HIGHLY RECOMMENDED... AND FOR GOOD REASONS



1. provides broad-spectrum, overlapping antibacterial effectiveness against common susceptible pathogens, including staph and strep
2. helps prevent topical infections, and treats those that have already started
3. it's good medicine for abrasions, lacerations, open wounds, primary pyodermas, secondarily infected dermatoses; and it's painless and cosmetically pleasing
4. contains three antibiotics that are rarely used systemically
5. you can recommend it in any of the three convenient package sizes: 1 oz tube, ½ oz tube, or the versatile, single-use foil packet

selected by NASA for the Apollo and Skylab missions

NEOSPORIN® Ointment

(polymyxin B-bacitracin-neomycin)

Each gram contains: Aerosporin® (Polymyxin B Sulfate) 5,000 units, bacitracin zinc 400 units, neomycin sulfate 5 mg (equivalent to 3.5 mg neomycin base); special white petrolatum qs; in tubes of 1 oz and 1/2 oz and 1/32 oz (approx.) foil packets.

WARNING: Because of the potential hazard of nephrotoxicity and ototoxicity due to neomycin, care should be exercised when using this product in treating extensive burns, trophic ulceration and other extensive conditions where absorption of neomycin is possible. In burns where more than 20 percent of the body surface is affected, especially if the patient has impaired renal function or is receiving other aminoglycoside antibiotics concurrently, not more than one application a day is recommended.

When using neomycin-containing products to control secondary infection in the chronic dermatoses, it should be borne in mind that the skin is more liable to become sensitized to many substances, including neomycin. The manifestation of sensitization to neomycin is usually a low grade reddening with swelling, dry scaling and itching; it may be manifest simply as a failure to heal. During long-term use of neomycin-containing products, periodic examination for such signs is advisable and the patient should be told to discontinue the product if they are observed. These symptoms regress quickly on withdrawing the medication. Neomycin-containing applications should be avoided for that patient thereafter.

PRECAUTIONS: As with other antibacterial preparations, prolonged use may result in overgrowth of nonsusceptible organisms, including fungi. Appropriate measures should be taken if this occurs.

ADVERSE REACTIONS: Neomycin is a not uncommon cutaneous sensitizer. Articles in the current literature indicate an increase in the prevalence of persons allergic to neomycin. Ototoxicity and nephrotoxicity have been reported (see Warning section).

AMA AMERICAN MEDICAL ASSOCIATION

PAIN GONE

while the antibiotic gets going

An effective adjuvant to systemic antibiotic treatment, AURALGAN promptly relieves the pain and reduces the inflammation of acute otitis media, while the antibiotic of choice fights the infection.

AURALGAN contains the topical analgesic action of benzocaine and antipyrine plus glycerin dehydrated...a decongestant so hygroscopic that it "blots up" excess moisture through the tympanic membrane, for relief of pressure and pain in the middle ear.

BRIEF SUMMARY
(For full prescribing information, see package circular.)
AURALGAN® Otic Solution
Each ml contains:
Antipyrine . . . . . 54.0 mg
Benzocaine . . . . . 14.0 mg
Glycerin dehydrated q.s. to. . . . . 1.0 ml
(contains not more than 1.0% moisture) (also contains oxyquinoline sulfate)
INDICATIONS: *Acute otitis media of various etiologies*
—prompt relief of pain and reduction of inflammation in the congestive and serous stages
—adjuvant therapy during systemic antibiotic administration for resolution of the infection
CONTRAINDICATIONS: Hypersensitivity to any of the components or substances related to them./In the presence of spontaneous perforation or discharge.
DOSAGE AND ADMINISTRATION: *Acute otitis media:* Instill AURALGAN, permitting the solution to run along the wall of the canal until it is filled. Avoid touching the ear with dropper. Then moisten a cotton pledget with AURALGAN and insert into meatus. Repeat every one to two hours until pain and congestion are relieved.
HOW SUPPLIED: No.1000—AURALGAN® Otic Solution, in package containing 15 ml (½ fl oz) bottle with separate dropper-screw cap attachment.

...in acute otitis media

Auralgan®

OTIC SOLUTION

FULLY COMPATIBLE WITH SYSTEMIC ANTIBACTERIAL THERAPY. ON PRESCRIPTION ONLY.

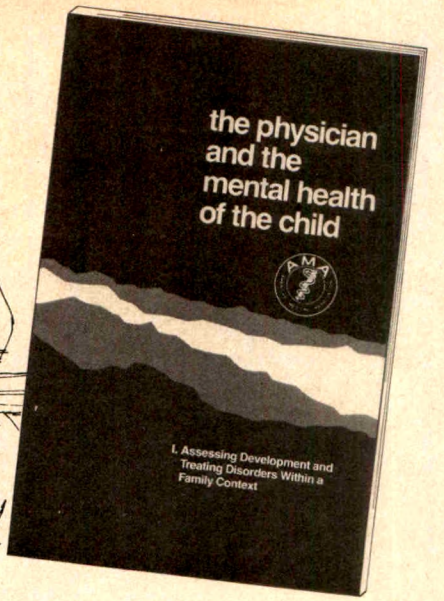
New! for primary care physicians



AN AUTHORITATIVE GUIDEBOOK ON THE MENTAL HEALTH OF CHILDREN

Since primary care physicians are usually the first health care professionals to see early disturbances in children, they need to be aware of developmental and emotional problems, particularly in children of pre-school age.

The *Physician and the Mental Health of the Child,* the first of a series of monographs based on the AMA Workshops on the Mental Health of Children, has been designed to provide current, authoritative information that may be useful to primary care physicians in their care of children.

Because any child must be seen as a developing human being and any pathology must be assessed in a developmental framework, much of this first monograph is devoted to developmental levels and problems and how they can be appropriately evaluated in the juvenile patient. Part I of the book gives both general and background material and overall information about children, as well as some "how to do it" details.

CONTENTS

Chapter I: Child and Family Assessment: The Family Inventory
A family inventory should be taken in addition to the medical history. The child who presents for treatment must be viewed in the context of the family of which he is a part: he cannot be viewed in isolation. A comprehensive family inventory helps to identify developmental problems in the child, while assessing the interplay of their multiple causes.

Chapter II: Assessing Developmental Levels
Chapter III: Developmental Tests
Developmental assessment should determine whether the child is progressing optimally in all regards, and, if not, the appropriate steps that can be taken to ameliorate problems and prevent serious pathology. Since the way a physician uses assessment procedures depends on training, experience and the extent to which he wishes to be involved in screening, development and guidance, recommendations are offered to help a physician assess development in accordance with his capabilities and interests. A summary of commonly used developmental tests is included.

Chapter IV: Assessing Developmental Problems
Not only must the child's current level of development be evaluated, but his innate strengths and weaknesses, and how the environment has supported or impeded development, need to be determined. The physician must help the child and his family utilize their resources and strengths to maintain health.

Chapter V: Assessing Parental Capabilities
Parental capabilities also need to be evaluated. If the physician believes there may be problems in the parent-child relationships, this concern should be shared with the parents in a non-judgmental and nonaccusatory way.

Chapter VI: Emotional Concomitants of Physical Illness
When formulating a treatment program for a child with emotional symptoms occuring primarily or secondarily with physical illness, the physician needs to consider the emotional reactions of the ill child. He should also be knowledgable about phase-specific developmental needs and tasks of the child; the individual personality characteristics of the child and parents; specific illness and treatment-based anxieties; and sociocultural characteristics of the family.

Chapter VII: Treating Children with Mental or Developmental Problems
The primary care physician should be familiar with the role of psychopharmacotherapy, environmental changes, supportive psychotherapy, behavioral modification, remedial education, marriage counseling and insight-producing psychotherapy, even if he does not wish to incorporate these psychological treatments into his practice. The dynamics of referral and consultation are also discussed.

Chapter VIII: Cultural Characteristics Affecting Patient Care
Chapter IX: Common Problems Affecting the Mental Health of Children in Non-Mainstream Families
Part II of *The Physician and the Mental Health of the Child* addresses the unique needs of the children in various ethnic groups, children coming from family situations and backgrounds largely unfamiliar to the average practicing physician—the urban poor, blacks, American-Indians, Mexican-Americans and single-parent families. The history of these families, their contacts with the health delivery system, particular developmental problems their children migh have and the appropriateness of the patterns of care they are now receiving are examined.

With the growth of third party payments, these patients will come increasingly to the attention of the primary care physician, who should be prepared to assess the impact of their cultural considerations and influences on the child's mental health. He should recognize also that particular ethnic groups may have unique patterns and problems.

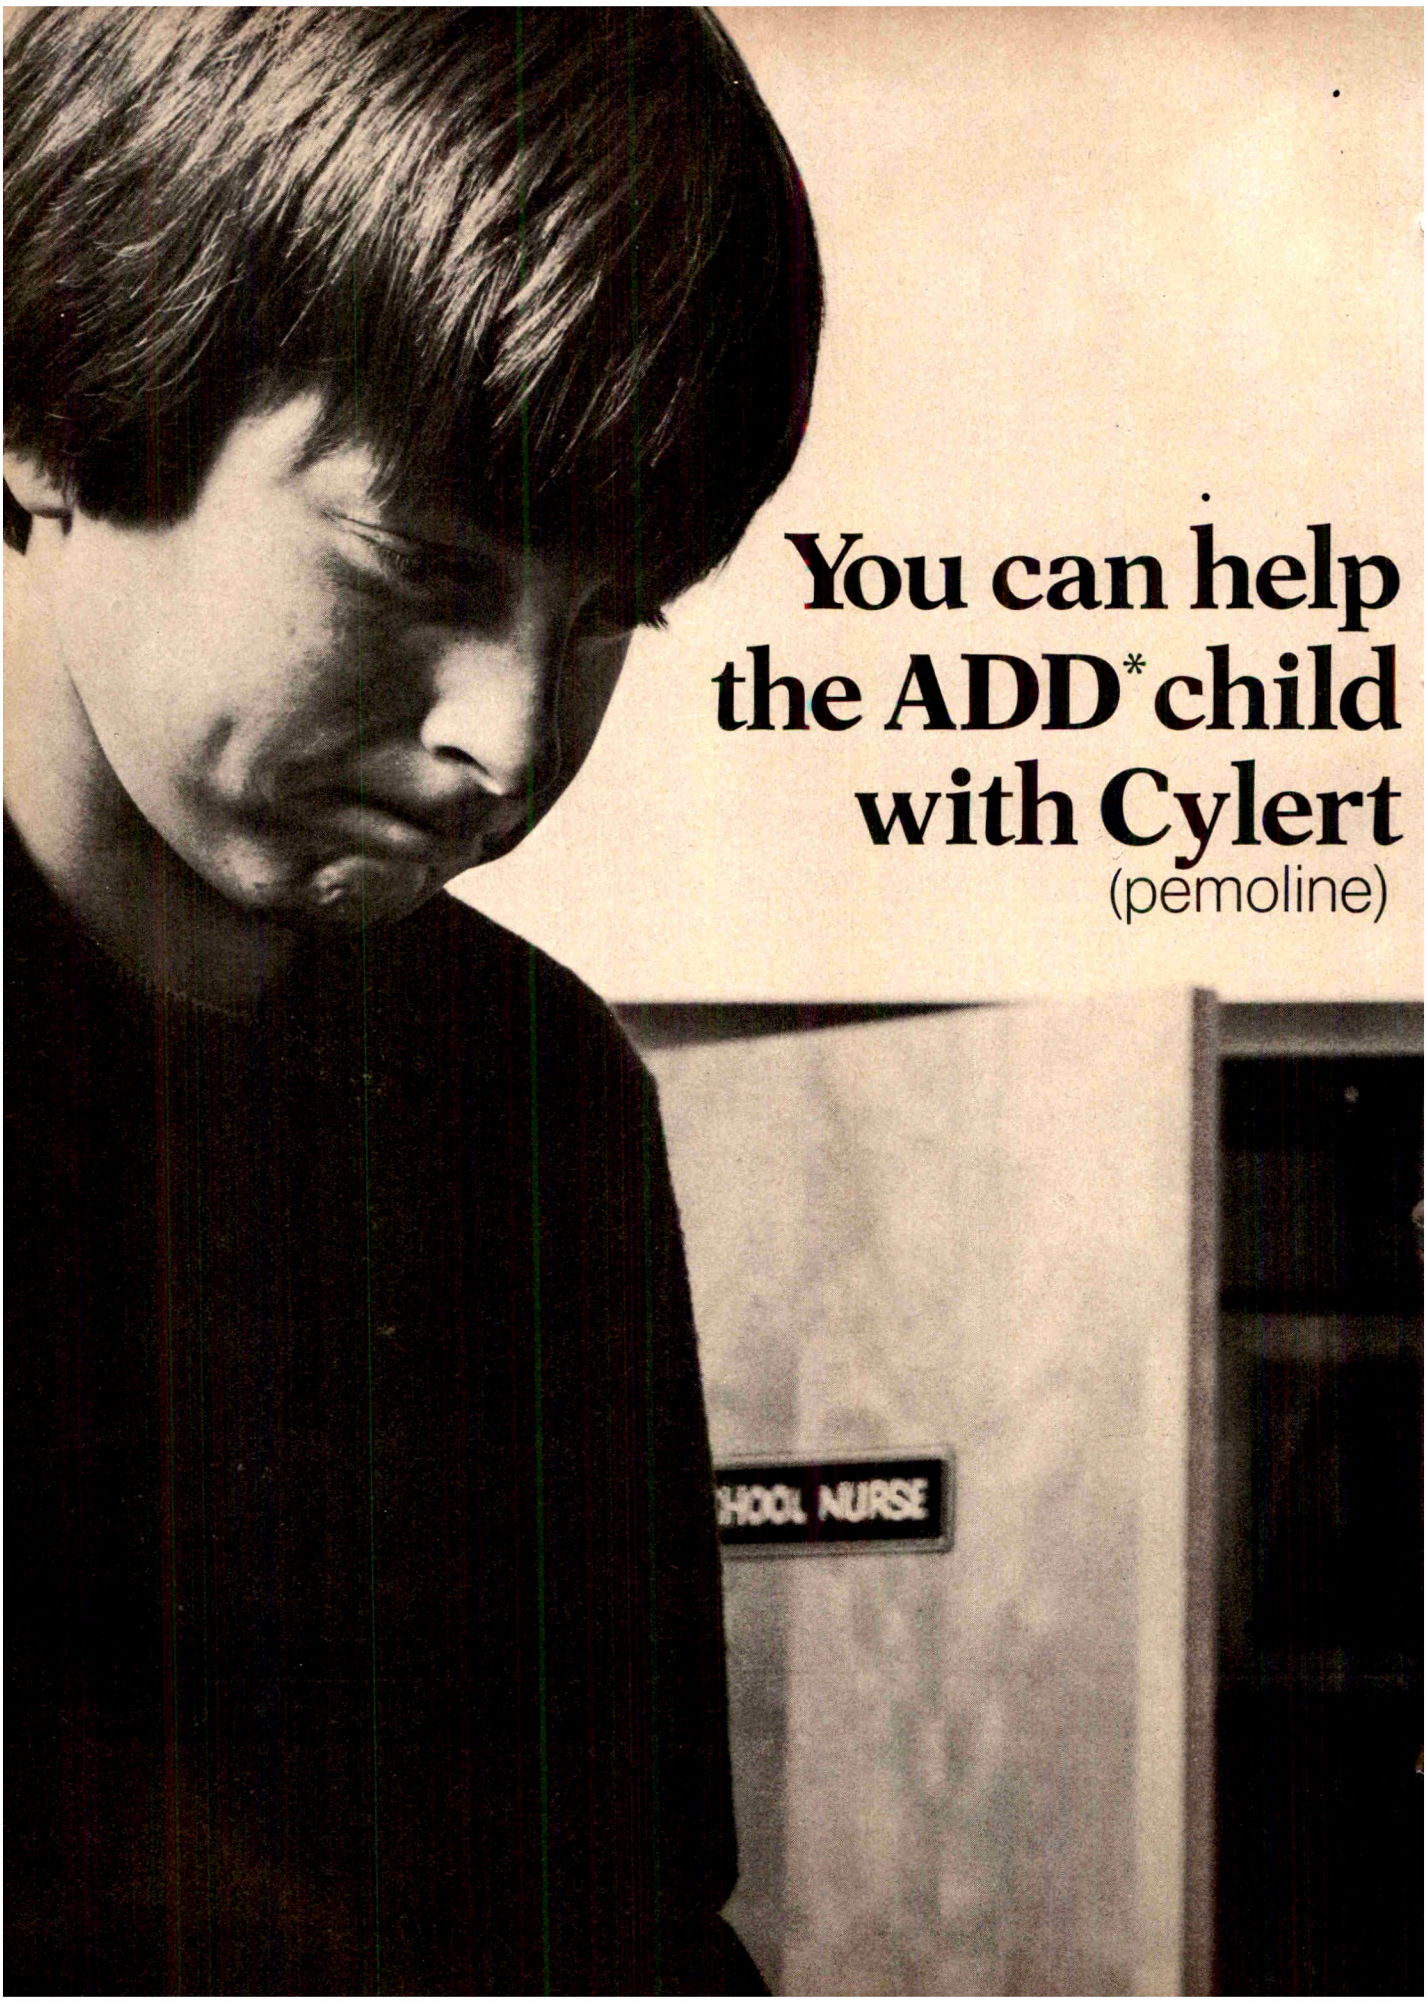
ONE HUNDRED YEARS WELLCOME

Burroughs Wellcome Co.
Research Triangle Park
North Carolina 27709



You can help the ADD* child with Cylert

(pemoline)

Day-long behavior therapy without dosing problems at school

Impressive all-day control.

Cylert works extremely well, given an adequate period of trial. Single daily doses are as effective for behavior control as multiple doses of methylphenidate or amphetamines. Blood levels are well sustained, without necessity for multidose administration.

No troublesome midday dose.

Cylert avoids problems of taking a drug at school. No involvement of school personnel. No peer teasing about noon-time dosing. The parents manage all medication, and the child carries no drugs. (And note that Cylert is Schedule IV, not II.)

Cylert® (pemoline) C IV

18.75, 37.5, 75 mg tablets; 37.5 mg chewables

Just once a day. At home.

*ADD: Attention Deficit Disorder (formerly called MBD, Minimal Brain Dysfunction), or the Hyperkinetic Syndrome. Please see next page for Brief Summary.

ABBOTT

9083319

Cylert® (pemoline)

DESCRIPTION: CYLERT (pemoline) is a central nervous system stimulant. Pemoline is structurally dissimilar to the amphetamines and methylphenidate.

It is an oxazolidine compound and is chemically identified as 2-amino-5-phenyl-2-oxazolin-4-one.

Pemoline is a white, tasteless, odorless powder, relatively insoluble (less than 1 mg./ml.) in water, chloroform, ether, acetone, and benzene; its solubility in 95% ethyl alcohol is 2.2 mg./ml.

CYLERT (pemoline) is supplied as tablets for oral administration.

CLINICAL PHARMACOLOGY: CYLERT (pemoline) has a pharmacological activity similar to that of other known central nervous system stimulants; however, it has minimal sympathomimetic effects. Although studies indicate that pemoline may act in animals through dopaminergic mechanisms, the exact mechanism and site of action of the drug in man is not known.

There is neither specific evidence which clearly establishes the mechanism whereby CYLERT produces its mental and behavioral effects in children, nor conclusive evidence regarding how these effects relate to the condition of the central nervous system.

The serum half-life of pemoline is approximately 12 hours. Peak serum levels of the drug occur within 2 to 4 hours after ingestion of a single dose. Multiple dose studies in adults at several dose levels indicate that steady state is reached in approximately 2 to 3 days.

Metabolites of pemoline include pemoline conjugate, pemoline dione, mandelic acid, and unidentified polar compounds. CYLERT is excreted primarily by the kidneys; approximately 75% of an oral dose is recovered in the urine within 24 hours. Approximately 43% of pemoline is excreted unchanged.

CYLERT (pemoline) has a gradual onset of action. Using the recommended schedule of dosage titration, significant clinical benefit may not be evident until the third or fourth week of drug administration.

INDICATIONS: CYLERT is indicated as an integral part of a total treatment program which typically includes other remedial measures (psychological, educational, social) for a stabilizing effect in children with a behavioral syndrome characterized by the following group of developmentally inappropriate symptoms: moderate to severe distractibility, short attention span, hyperactivity, emotional lability, and impulsivity. The diagnosis of this syndrome should not be made with finality when these symptoms are only of comparatively recent origin. Nonlocalizing (soft) neurological signs, learning disability, and abnormal EEG may or may not be present, and a diagnosis of central nervous system dysfunction may or may not be warranted.

Attention Deficit Disorder and Hyperkinetic Syndrome are among the terms being used to describe the above signs and symptoms. In the past, a variety of terms has been associated with these signs and symptoms, including: Minimal Brain Dysfunction, Hyperkinetic Reaction of Childhood, Hyperkinetic Syndrome, Hyperactive Child Syndrome, Minimal Brain Damage, Minimal Cerebral Dysfunction, and Minor Cerebral Dysfunction.

CONTRAINDICATIONS: CYLERT (pemoline) is contraindicated in patients with known hypersensitivity or idiosyncrasy to the drug. (See ADVERSE REACTIONS.)

WARNINGS: CYLERT is not recommended for children less than 6 years of age since its safety and efficacy in this age group have not been established.

Clinical experience suggests that in psychotic children, administration of CYLERT may exacerbate symptoms of behavior disturbance and thought disorder.

Data are inadequate to determine whether chronic administration of CYLERT may be associated with growth inhibition; therefore, growth should be monitored during treatment.

PRECAUTIONS: Drug treatment is not indicated in all cases of the behavioral syndrome characterized by moderate to severe distractibility, short attention span, hyperactivity, emotional lability and impulsivity. It should be considered only in light of the complete history and evaluation of the child. The decision to prescribe CYLERT should depend on the physician's assessment of the chronicity and severity of the child's symptoms and their appropriateness for his/her age. Prescription should not depend solely on the presence of one or more of the behavioral characteristics.

When these symptoms are associated with acute stress reactions, treatment with CYLERT is usually not indicated.

Long-term effects of CYLERT in children have not been well established.

Liver function tests should be performed prior to and periodically during therapy with CYLERT. The drug should be discontinued if abnormalities are revealed and confirmed by follow-up tests. (See ADVERSE REACTIONS regarding reports of abnormal liver function tests and jaundice.)

CYLERT should be administered with caution to patients with significantly impaired hepatic or renal function.

The interaction of CYLERT with other drugs has not been studied in humans. Patients who are receiving CYLERT concurrently with other drugs, especially drugs with CNS activity, should be monitored carefully.

CYLERT failed to demonstrate a potential for self-administration in primates. However, the pharmacologic similarity of pemoline to other psychostimulants with known dependence liability suggests that psychological and/or physical dependence might also occur with CYLERT. There have been isolated reports of transient psychotic symptoms occurring in adults following the long-term misuse of excessive oral doses of pemoline. CYLERT should be given with caution to emotionally unstable patients who may increase the dosage on their own initiative.

Usage during Pregnancy and Lactation: The safety of CYLERT (pemoline) for use during pregnancy and lactation has not been established.

Studies in rats have shown an increased incidence of stillbirths and cannibalization when pemoline was administered at a dose of 37.5 mg./kg./day. Postnatal survival of offspring was reduced at doses of 18.75 and 37.5 mg./kg./day.

ADVERSE REACTIONS: Insomnia is the most frequently reported side effect of CYLERT; it usually occurs early in therapy, prior to an optimum therapeutic response. In the majority of cases it is transient in nature or responds to a reduction in dosage.

Anorexia with weight loss may occur during the first weeks of therapy. In the majority of cases it is transient in nature; weight gain usually resumes within three to six months.

Stomach ache, skin rashes, increased irritability, mild depression, nausea, dizziness, headache, drowsiness, and hallucinations have been reported.

Elevations of SGOT, SGPT, and serum LDH have occurred in patients taking CYLERT, usually after several months of therapy. These effects appear to be reversible upon withdrawal of the drug, and are thought to be manifestations of a delayed hypersensitivity reaction. There have also been a few reports of jaundice occurring in patients taking CYLERT; a causal relationship between the drug and this clinical finding has not been established.

The following CNS effects have been reported with the use of CYLERT: dyskinetic movements of the tongue, lips, face and extremities, nystagmus and nystagmoid eye movements, and convulsive seizures. A definite causal relationship between CYLERT and these reactions has not been established.

Mild adverse reactions appearing early during the course of treatment with CYLERT often remit with continuing therapy. If adverse reactions are of a significant or protracted nature, dosage should be reduced or the drug discontinued.

OVERDOSAGE: Signs and symptoms of acute CYLERT overdosage may include agitation, restlessness, hallucinations, dyskinetic movements and tachycardia. The treatment for an acute overdosage of pemoline is essentially the same as that for an overdosage of any CNS stimulant. Management is primarily symptomatic and may include induction of emesis or gastric lavage, sedation, and other appropriate supportive measures.

Results of studies in dogs indicate that extracorporeal hemodialysis may be useful in the management of CYLERT overdosage; forced diuresis and peritoneal dialysis appear to be of little value.

DOSAGE AND ADMINISTRATION: CYLERT (pemoline) is administered as a single oral dose each morning. The recommended starting dose is 37.5 mg./day. This daily dose should be gradually increased by 18.75 mg. at one week intervals until the desired clinical response is obtained. The effective daily dose for most patients will range from 56.25 to 75 mg. The maximum recommended daily dose of pemoline is 112.5 mg.

Clinical improvement with CYLERT is gradual. Using the recommended schedule of dosage titration, significant benefit may not be evident until the third or fourth week of drug administration.

Where possible, drug administration should be interrupted occasionally to determine if there is a recurrence of behavioral symptoms sufficient to require continued therapy.

Announcing two new
MONOGRAPHS IN NEONATOLOGY
Thomas K. Oliver, M.D. -Series Consultant

Neonatal Necrotizing Enterocolitis

Edited by EDWIN G. BROWN, M.D. and AVRON Y. SWEET, M.D.

Throughout North America and abroad, neonatal necrotizing enterocolitis is endemic in most nurseries that treat sick newborn infants. The disease has become an important cause of morbidity and mortality. *Neonatal Necrotizing Enterocolitis* provides a complete presentation of the disease: its historical background, epidemiology, causation, x-ray findings, pathology, clinical picture, treatment, and prevention. The book discusses the epidemiology in light of current understanding. It describes the circulatory basis of the disease and clearly demonstrates the consequences of intestinal ischemia. It further develops the pathogenesis in its detailed and scholarly presentation of the role of the intestinal microflora, the factors that influence it, and its effects of the alimentary tract. Included in this discussion is a brief but important treatment of endotoxin. Finally, the book provides a detailed discussion of the influence of feeding practices.

1980, 224 pp., $21.50 ISBN: 0-8089-1244-5

Neonatal Hyperbilirubinemia

By GERARD B. ODELL, M.D.

CONTENTS: Preface. Jaundice and the Formation and Excretion of Bilirubin. Bilirubin Metabolism During Fetal Life. Normal Metabolism of Bilirubin During Neonatal Life. Abnormal Metabolism of Bilirubin During Neonatal Life. Toxicity of Bilirubin and Assessment of its risk During Neonatal Life. Treatment of Neonatal Hyperbilirubinemia. Conclusion. Appendix I. Appendix II.

1980, 176 pp., $16.50 ISBN: 0-8089-1247-X

Future volumes in MONOGRAPHS IN NEONATOLOGY are now available on a Continuation Order basis. Your Continuation Order authorizes us to ship and bill each future volume in the series automatically, immediately upon publication. This order will remain in effect until cancelled. Specify the volume title with which your order is to begin.

Instructions for Authors

General Information.—Send manuscripts by first-class (**not** registered) mail to the Chief Editor, Gilbert B. Forbes, MD, Box 777, 601 Elmwood Ave, Rochester, NY 14642. Designate one author as correspondent and provide his/her address and telephone number. Manuscripts are received with the understanding that they are not under simultaneous consideration by another publication. Accepted manuscripts become the permanent property of the *American Journal of Diseases of Children* and may not be published elsewhere without permission from the publisher (AMA).

In view of the provisions of *The Copyright Revision Act of 1976*, effective Jan 1, 1978, the author(s) of manuscripts, letters to the editor, and book reviews accepted for publication in the JOURNAL will be required to sign and date the following statement: "In consideration of the AMA taking action in reviewing and editing my/our submission, the author(s) undersigned hereby transfers, assigns, or otherwise conveys all copyright ownership to the AMA in the event that such work is published by the AMA."

Manuscript Preparation

All the elements of a manuscript should be submitted in **triplicate, double-spaced throughout.** Use heavy-duty white bond paper, 22 × 28-cm, and 4-cm margins. The style of writing should conform to proper English usage and syntax. All measurements are to be in metric units, temperatures in Centigrade.

All accepted manuscripts are subject to copy editing. The corresponding author will receive an edited typescript and layout for approval. Forms for ordering reprints are included with the edited typescript. Proofs will be sent for approval if requested by the author and if printing deadlines permit. The author is responsible for all statements in his/her work, including changes made by the copy editor.

Titles.—Titles should be short, specific, and clear. They should not exceed 42 characters per line, including punctuation and spaces, and be limited to two lines. The title page should include the full names and academic affiliations of all authors, the address to which requests for reprints should be sent, and, if the manuscript was presented at a meeting, the name of the organization, place, and date on which it was read.

Abstract.—Provide an abstract (135-word maximum) of the article, including statement of the problem, method of study, results, and conclusions. The abstract replaces the summary.

Informed Consent.—Manuscripts reporting the results of experimental investigations on humans must include a statement to the effect that informed consent was obtained from the parents or guardians after the nature of the procedure(s) had been fully explained.

Clinical Memoranda

Brief accounts of interesting observations and clinical situations. Limited to 800 words plus one table or illustration; abstract unnecessary. Submit in triplicate, double-spaced. Copyright assignment required.

Letters to the Editor

Correspondence pertaining to material published in the JOURNAL. Limit 500 words. Submit in triplicate, double-spaced, and clearly marked "For publication." Copyright assignment required.

References

These must be listed in order of their appearance in the text, and typed double-spaced, in the following manner:

1. Applebaum MM, Thaler MM: Reye syndrome without initial hepatic involvement. *Am J Dis Child* 131:295-296, 1977.
2. Koller LR: *Ultraviolet Radiation*, ed 2. New York, John Wiley & Sons Inc, 1965, pp 141-160.
3. Daughaday WH: The adenohypophysis, in Williams RH (ed): *Textbook of Endocrinology*, ed 5. Philadelphia, WB Saunders Co, 1974, pp 31-79.

Do not include unpublished data, personal communications, or manuscripts "in preparation" or "submitted" in the list of references. Such material, if essential, may be incorporated in the body of the article.

Illustrations

Submit in triplicate, unmounted, and untrimmed. Send only high contrast glossy prints (not photocopies or original artwork); preferred size 12.5 × 18-cm. Figure number, name of first author, and arrow indicating "top" should be typed on a gummed label and affixed to the back of each illustration. Lettering must be legible after reduction to column size. Magnification and stain should be provided for histologic sections.

For illustrations in full color submit 35-mm, positive color transparencies, mounted in cardboard and carefully packaged. Do not submit glass-mounted transparencies; do not submit color prints. The fee is $275 for up to six square-finished color illustrations that can be arranged on one page.

Legends.—Legends for illustrations should be typed double-spaced, beginning on a separate sheet of paper (40-word maximum for each).

Acknowledgments.—Illustrations and tables from other publications must be suitably acknowledged, and accompanied by written permission from publisher and author.

Photographic Consents.—A signed statement of consent from **both** parents (or guardian) or the persons involved must accompany all photographs of patients in which a possibility of identification exists. It is not sufficient to cover the eyes to mask identity.

Tables.—Each table should be typed double-spaced, including all headings, on a separate sheet of 22 × 28-cm paper. If a table must be continued, use a second sheet and repeat all heads. Each table must have a title.

NOW PETER

Attention Deficit Disorders* under control...
His natural abilities are coming through

Now Peter's enjoying more things at play as well as in school. He works better with his teacher and classmates... likes doing things with his dad... gets more natural pleasure out of family and friends.

Now that his concentration is improved, his natural abilities are coming through. He's functioning better. Under a well-integrated program of treatment for Attention Deficit Disorders (ADD), hyperactivity and impulsiveness are markedly reduced.

Ritalin (methylphenidate) can be a vital part of his regimen. With adjunctive use of Ritalin, many ADD children are better able to control hyperkinetic behavior —act in a more natural and appropriate manner.

A 20-year record of proven efficacy

Over the years, Ritalin has become an established choice for pharmacotherapy of ADD. In a report by the

BEHAVES MORE NATURALLY.

National Council on Child Health,[1] Ritalin was described as among the most effective and best-documented agents for stimulant therapy in hyperkinetic children.

Reduces hyperactivity, impulsive behavior

Ritalin has a well-documented record of success in relieving the dominant symptoms of ADD. As it reduces distractibility, disorganized behavior and hyperactivity, improved school performance usually results,[2,3] as well as better peer interaction.[2]

Generally well tolerated

Although side effects may occur with Ritalin, they are generally not serious. During prolonged therapy, anorexia, weight loss, and insomnia are among the most frequently encountered adverse reactions. (See Adverse Reactions section of the prescribing information.) Even though most children require long-term treatment, there is little evidence of habituation.[1]

Therapy with Ritalin should be considered only after a medical diagnosis of ADD has been confirmed. Dosage can usually be interrupted during weekends and vacations. In some cases, these drug holidays reveal "stabilization" in the child's behavior without medication. They may permit a reduction in dosage and eventual discontinuation of drug therapy if warranted.

***Attention Deficit Disorders:** new designation by the American Psychiatric Association; formerly called Minimal Brain Dysfunction (MBD) or Hyperkinetic Syndrome.

Ritalin . . . only when medication is indicated for Attention Deficit Disorders

Ritalin® C II
(methylphenidate)
as adjunctive therapy for ADD

Please turn page for brief prescribing information

Ritalin® C II
(methylphenidate)
Only when medication is indicated

Ritalin® hydrochloride (methylphenidate hydrochloride USP) C II

TABLETS

INDICATIONS

Attention Deficit Disorders (previously known as Minimal Brain Dysfunction in Children). Other terms being used to describe the behavioral syndrome below include: Hyperkinetic Child Syndrome, Minimal Brain Damage, Minimal Cerebral Dysfunction, Minor Cerebral Dysfunction.

Ritalin is indicated as an integral part of a total treatment program which typically includes other remedial measures (psychological, educational, social) for a stabilizing effect in children with a behavioral syndrome characterized by the following group of developmentally inappropriate symptoms: moderate-to-severe distractibility, short attention span, hyperactivity, emotional lability, and impulsivity. The diagnosis of this syndrome should not be made with finality when these symptoms are only of comparatively recent origin. Nonlocalizing (soft) neurological signs, learning disability, and abnormal EEG may or may not be present, and a diagnosis of central nervous system dysfunction may or may not be warranted.

Special Diagnostic Considerations

Specific etiology of this syndrome is unknown, and there is no single diagnostic test. Adequate diagnosis requires the use not only of medical but of special psychological, educational, and social resources.

Characteristics commonly reported include: chronic history of short attention span, distractibility, emotional lability, impulsivity, and moderate-to-severe hyperactivity; minor neurological signs and abnormal EEG. Learning may or may not be impaired. The diagnosis must be based upon a complete history and evaluation of the child and not solely on the presence of one or more of these characteristics.

Drug treatment is not indicated for all children with this syndrome. Stimulants are not intended for use in the child who exhibits symptoms secondary to environmental factors and/or primary psychiatric disorders, including psychosis. Appropriate educational placement is essential and psychosocial intervention is generally necessary. When remedial measures alone are insufficient, the decision to prescribe stimulant medication will depend upon the physician's assessment of the chronicity and severity of the child's symptoms.

CONTRAINDICATIONS

Marked anxiety, tension, and agitation are contraindications to Ritalin, since the drug may aggravate these symptoms. Ritalin is contraindicated also in patients known to be hypersensitive to the drug and in patients with glaucoma.

WARNINGS

Ritalin should not be used in children under six years, since safety and efficacy in this age group have not been established.

Sufficient data on safety and efficacy of long-term use of Ritalin in children are not yet available. Although a causal relationship has not been established, suppression of growth (*ie*, weight gain, and/or height) has been reported with the long-term use of stimulants in children. Therefore, patients requiring long-term therapy should be carefully monitored.

Ritalin should not be used for severe depression of either exogenous or endogenous origin. Clinical experience suggests that in psychotic children, administration of Ritalin may exacerbate symptoms of behavior disturbance and thought disorder.

Ritalin should not be used for the prevention or treatment of normal fatigue states.

There is some clinical evidence that Ritalin may lower the convulsive threshold in patients with prior history of seizures, with prior EEG abnormalities in absence of seizures, and, very rarely, in absence of history of seizures and no prior EEG evidence of seizures. Safe concomitant use of anticonvulsants and Ritalin has not been established. In the presence of seizures, the drug should be discontinued.

Use cautiously in patients with hypertension. Blood pressure should be monitored at appropriate intervals in all patients taking Ritalin, especially those with hypertension.

Symptoms of visual disturbances have been encountered in rare cases. Difficulties with accommodation and blurring of vision have been reported.

Drug Interactions

Ritalin may decrease the hypotensive effect of guanethidine. Use cautiously with pressor agents and MAO inhibitors.

Human pharmacologic studies have shown that Ritalin may inhibit the metabolism of coumarin anticoagulants, anticonvulsants (phenobarbital, diphenylhydantoin, primidone), phenylbutazone, and tricyclic antidepressants (imipramine, desipramine). Downward dosage adjustments of these drugs may be required when given concomitantly with Ritalin.

Usage in Pregnancy

Adequate animal reproduction studies to establish safe use of Ritalin during pregnancy have not been conducted. Therefore, until more information is available, Ritalin should not be prescribed for women of childbearing age unless, in the opinion of the physician, the potential benefits outweigh the possible risks.

Drug Dependence

Ritalin should be given cautiously to emotionally unstable patients, such as those with a history of drug dependence or alcoholism, because such patients may increase dosage on their own initiative.

Chronically abusive use can lead to marked tolerance and psychic dependence with varying degrees of abnormal behavior. Frank psychotic episodes can occur, especially with parenteral abuse. Careful supervision is required during drug withdrawal, since severe depression as well as the effects of chronic overactivity can be unmasked. Long-term follow-up may be required because of the patient's basic personality disturbances.

PRECAUTIONS

Patients with an element of agitation may react adversely; discontinue therapy if necessary.

Periodic CBC, differential, and platelet counts are advised during prolonged therapy.

Drug treatment is not indicated in all cases of this behavioral syndrome and should be considered only in light of the complete history and evaluation of the child. The decision to prescribe Ritalin should depend on the physician's assessment of the chronicity and severity of the child's symptoms and their appropriateness for his/her age. Prescription should not depend solely on the presence of one or more of the behavioral characteristics.

When these symptoms are associated with acute stress reactions, treatment with Ritalin is usually not indicated.

Long-term effects of Ritalin in children have not been well established.

The Ritalin tablets (5 and 20 mg) contain FD&C Yellow No. 5 (tartrazine) which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals. Although the overall incidence of FD&C Yellow No. 5 (tartrazine) sensitivity in the general population is low, it is frequently seen in patients who also have aspirin hypersensitivity.

ADVERSE REACTIONS

Nervousness and insomnia are the most common adverse reactions but are usually controlled by reducing dosage and omitting the drug in the afternoon or evening. Other reactions include hypersensitivity (including skin rash, urticaria, fever, arthralgia, exfoliative dermatitis, erythema multiforme with histopathological findings of necrotizing vasculitis, and thrombocytopenic purpura); anorexia; nausea; dizziness; palpitations; headache; dyskinesia; drowsiness; blood pressure and pulse changes, both up and down; tachycardia; angina; cardiac arrhythmia; abdominal pain; weight loss during prolonged therapy. Toxic psychosis has been reported. Although a definite causal relationship has not been established, the following have been reported in patients taking this drug: leukopenia and/or anemia; a few instances of scalp hair loss.

In children, loss of appetite, abdominal pain, weight loss during prolonged therapy, insomnia, and tachycardia may occur more frequently; however, any of the other adverse reactions listed above may also occur.

DOSAGE AND ADMINISTRATION

Children (6 years and over)

Start with small doses (*eg*, 5 mg before breakfast and lunch) with gradual increments of 5 to 10 mg weekly. Daily dosage above 60 mg is not recommended. If improvement is not observed after appropriate dosage adjustment over a one-month period, the drug should be discontinued.

If paradoxical aggravation of symptoms or other adverse effects occur, reduce dosage, or, if necessary, discontinue the drug.

Where possible, drug administration should be interrupted occasionally to determine if there is a recurrence of behavioral symptoms sufficient to require continued therapy. Improvement may be sustained when the drug is either temporarily or permanently discontinued.

Drug treatment should not and need not be indefinite and usually may be discontinued after puberty.

HOW SUPPLIED

Tablets, 20 mg (peach, scored); bottles of 100 and 1000.

Tablets, 10 mg (pale green, scored); bottles of 100, 500, 1000 and Accu-Pak® blister units of 100.

Tablets, 5 mg (pale yellow); bottles of 100, 500 and 1000.

Dispense in tight, light-resistant container (USP).

665382 C80-14 (1/80)

Consult complete product literature before prescribing.

Inhibition of Iron Absorption by Certain Foods

The article of Oski and Landaw (see p 459) and the recently published report by Saarinen and Siimes[1] indicate that the timing and choice of solid foods for infants may have a much greater influence on iron nutrition than was previously realized. In early infancy, most of the demands of iron for growth are supplied by relatively abundant neonatal iron stores, and absorption of food iron plays a subsidiary role.[2] As neonatal stores become depleted after about four months in the term infant, iron must be supplied almost exclusively from dietary sources. The transition between these two phases of iron metabolism coincides with the time when the introduction of solid foods is currently recommended.[3,4]

Absorption of food iron is under two major influences: the first is the homeostatic function of the intestinal mucosa, by which the absorption of iron increases as iron stores decrease; second and less widely appreciated is the interaction of food iron with other dietary constituents. This interaction plays as important a role as the actual iron content of the diet.[4] Oski and Landaw measured the absorption of iron in a group of adult subjects from breast milk alone and breast milk fed with strained pears. The absorption from breast milk alone was about four times greater than when breast milk was administered with pears at the same time. Despite the fact that breast milk contains only a small amount of iron (0.5 mg/L during the first month after birth, decreasing to about 0.3 mg/L when the child is between 4 and 6 months of age),[5] the percent absorbed has a significant impact on iron nutrition because milk accounts for almost all of the infant's diet during this period. Studies of infants fed primarily breast milk show that an average of about 50% of the iron in breast milk is absorbed,[6] a remarkably high figure, compared with 12% from unfortified cow's milk formula.[7] The data of Oski and Landaw indicate that introduction of some solid foods in a breast-fed baby could compromise this excellent iron absorption. Similar conclusions emerge from the studies of Saarinen and Siimes,[1] who estimated the rate of increase in total body iron during the four-month period spanning the introduction of solid foods. When total body iron was calculated from hemoglobin concentration, serum ferritin, and body weight, it was found that the rate of iron accumulation decreased in breast-fed infants when unfortified solid foods (primarily fruits and vegetables) were introduced.

The clinical implications of the two studies are fortunately in line with current recommendations for infant feeding, particularly in respect to the benefits of prolonging the duration of breast feeding[8] and delaying the initiation of solid foods.[3,4] The advantages of breast feeding have been discussed in a recent review.[8] However, it is worth emphasizing that there is a marked disparity between current recommendations and common practices.[9] Many of the advantages of breast feeding may not fully apply if it is maintained for only one or two months, as is commonly the case, rather than six months or more as recommended.[8] Similarly, numerous surveys indicate that well over half the infants have had solid foods introduced before two months of age,[10] whereas the introduction of solid foods is recommended between four and six months of age.[3,4] Although the excessively early introduction of some solid foods is likely to compromise iron absorption unnecessarily, the breast-fed infant does eventually require additional sources of food iron. After six months of age, the iron available from

breast milk alone is insufficient to prevent consistently the depletion of iron stores and some degree of iron-restricted hemoglobin production.[11]

What are some reasonable choices among infant foods that are likely to meet iron needs and are also consistent with good overall nutrition? Most of the relevant studies of iron absorption from individual foods and from mixed meals have been done in adults and have shown that the iron content of foods gives little indication of how much will be absorbed. The percentage of iron absorbed from individual foods varies over at least a 20-fold range.[12] Among individual foods, iron is best absorbed from meat and is less well absorbed from vegetable and dairy foods. The interaction of foods in each meal is also important and has a major effect on the iron absorbed from the meal as a whole. Iron absorption studies from composite meals indicate that meat and ascorbic acid will enhance absorption of iron from the *entire* meal, whereas milk and other dairy products have the reverse effect.[13,14] For example, the presence of meat, poultry, or fish resulted in the absorption of about four times as much iron from a standard meal as the substitution of equivalent portions of cheese, milk, or eggs.[13] Orange juice with a meal more than doubled the iron absorbed from the entire meal.[14] Two of the traditional sources of iron in the infant diet, spinach[12] and egg[14,15] (yolk) have been discredited. Although both foods are rich in iron, the iron is in a form that is not well absorbed.

It would be helpful to have more information about iron absorption from single foods and food combinations in infants. However, even with what is known at present, some feeding patterns can be favored over others. In terms of iron status as well as general nutrition, current recommendations for more prolonged breast feeding[8] and later introduction of solid foods[3,4] deserve support. Recommendations covering broader aspects of iron nutrition in infancy were discussed in a recent statement of the Committee on Nutrition,[16] but the influence of solid foods (other than iron-fortified cereal) received little attention. When solid food is started between about four and six months of age, iron-fortified dry infant cereal seems a good first choice.[16] In a Norwegian study, a form of iron-fortified cereal was shown to be effective in preventing iron deficiency in infancy[17] and more recent studies in infants suggest that the percentage of iron absorbed from cereal is in the same general range as the absorption of iron from iron-fortified cow's milk formulas.[18] It may prove beneficial in the future to fortify dry infant cereals with ascorbic acid in addition to iron, to enhance iron absorption. This is currently being done with weaning foods distributed by some international and bilateral agencies, eg, United States Agency for International Development.[19] After several additional solid foods have been gradually introduced, after 6 months of age it seems a good idea to offer one meal of solid foods a day that does not include milk but substitutes water or orange juice as a beverage. This meal could include both iron-fortified dry infant cereal and orange juice (or other ascorbic acid-rich food) or iron-fortified cereal and meat; fruit or vegetable could also be included.

There are a variety of options for avoiding iron deficiency in infancy.[16] In the term breast-fed infant, this type of dietary regimen should eliminate the need for iron drops. Similar considerations should apply to the selection of solid foods for term infants who are fed formula without added iron. Infants who are fed iron-fortified formula have an ample supply of iron, and are less dependent on additional iron from solid foods. Any of these alternative feeding regimens should successfully bridge the period of tenuous iron balance during late infancy.

New Thoughts on Aspirin

Aspirin continues to hold its place as a cheap and effective way of treating patients with juvenile arthritis. The article by Doughty and his colleagues in this issue (p 461) reiterates aspirin's effectiveness and gives us a number of practical points in its usage.

Although rheumatologists (and Jane Schaller recently for children[1]) have often pointed out the desirability of maintaining serum salicylate levels between 20 and 30 mg/dL, this report satisfactorily establishes these limits. Most important is the upper limit where the authors have shown that there is no significant improvement in clinical response with salicylate levels higher than 30 mg/dL. When other nonsteroidal anti-inflammatory drugs were not available for the treatment of juvenile arthritis, it was thought to be worthwhile to try to push aspirin levels higher than 30 mg/dL. However, with the availability of at least one of the newer agents, tolmetin sodium,[2] it probably is inadvisable to continue aspirin therapy if a child is not doing well at levels close to 30 mg/dL, or when aspirin toxicity appears within the therapeutic limits. In this study, 16% of the children were forced to stop aspirin therapy because of side effects. This is remarkably close to the number of patients who were withdrawn from an aspirin regimen in a double-blind study against a nonsteroidal anti-inflammatory drug where the aspirin withdrawal rate was 11%. In that study, aspirin was given at an average dose of 90 mg/kg. However, in the study by Doughty et al almost 30% of the patients required doses in excess of this level to maintain salicylate levels greater than 20 mg/dL (their lower limit). To further confuse this issue, Makela and her colleagues[3] reported that at dosages of aspirin in a range similar to those used in the Schaller[1] and Levinson et al[2] studies, salicylism appeared in about 50% of the patients. This may have been a peculiarity of their patient population since they also believed that maximum therapeutic levels should be close to 30 mg/dL (in their case, 27 mg/dL).

When all of these recent reports are digested, we can see that aspirin therapy in children with juvenile arthritis can be placed on a firm footing. It appears wise to start children at dosages not higher than 90 mg/kg. If compliance can be assured, a serum salicylate level obtained about two weeks after onset of aspirin therapy (to allow for equilibration) will provide a further clue to proper dosage levels. If the level is less than 20 mg/dL, then one should increase the dosage to about 100 mg/kg/day. Taking a repeated serum salicylate level after several weeks indicates whether the optimum therapeutic levels have been reached. If the level continues to be less than 20 mg/dL, then, as pointed out by Doughty et al, dosages greater than 100 mg/kg/day will be required; and this was necessary in 30% of the patients they treated. Nausea or vomiting may be an indication of hepatotoxicity, and liver function studies should be done if this occurs. These children, according to Doughty and his co-workers, could be receiving choline salicylate therapy with improvement in the liver chemistries and no recurrence of symptoms while still achieving adequate therapeutic salicylate levels.

It should be mentioned that recent reports show that in those children who are old enough to swallow tablets, enteric-coated aspirin may be a safer and easier way to give the drug. Gastroscopic studies in adults have shown that there is significantly less irritation of and ulcer formation in the gastric mucosa with the use of enteric-coated aspirin.[4] Serum salicylate levels achieved with this preparation were comparable to those achieved with regular or buffered aspirin. Orozco-Alcala and Baum[5] similarly showed that enteric-coated aspirin produced levels similar to those obtained with regular and buffered aspirin and also pointed out that there was a higher degree of acceptance in children with this preparation, which is easier to swallow because of the smooth coating.

Injuries in High School Physical Education Classes

Gregory J. Austin; Kenneth D. Rogers, MD; Grace Reese, RN

• **Suburban high school pupils participating in physical education classes sustained 3.6 injuries per 100 participants per year that were noted on official school accident reports, and 5.4 injuries per 100 for which pupils visited the school nurse. These latter injuries were minor. The official school accident reports indicated that injuries occurred at approximately equal rates in boys and girls; most were due to accidents that did not involve another participant or a piece of sports equipment, and, although usually not severe, were referred by the school nurse for further evaluation or treatment in some cases. Sprains were the most common type of injury and the ankle was the most commonly injured area. No particular set of conditions was identified wherein preventive measures could be taken to decrease the injury rate.**

(*Am J Dis Child* 134:456-458, 1980)

Although injuries of high school pupils associated with participation in organized sports have been well described,[1-9] similar information has not been reported for injuries associated with participation in physical education classes. We studied the incidence and characteristics of injuries of suburban high school pupils that were related to their participation in physical education classes.

SUBJECTS AND METHODS

The study population included approximately 1,870 predominately white, middle-class pupils who attended a suburban Pittsburgh high school between September 1976 and June 1978. Pupils were required to participate in physical education classes during two 56-minute periods each week. Approximately 1% of all pupils were exempted from physical education class for chronic medical problems or independent study programs, and about 6% were absent from class on an average day. The usual activity time in a physical education class, allowing for changing clothes and roll call, was approximately 40 minutes. Thus, a 36-week school year resulted in a maximum of about 48 hours of physical education activity.

In each segment of the school year, pupils were allowed to choose between several kinds of physical education activity. During unsuitable weather, sports such as basketball, volleyball, table tennis, and dodgeball were substituted for outdoor activities. Usual physical education activities included field hockey, soccer, softball, touch football, gymnastics, swimming, basketball, wrestling, volleyball, track, and racket sports. Because of variation in activities and variation in attendance, it was not possible to calculate accurately the number of participants or the hours of participation associated with specific activities.

Two sources of data were used: official school accident injury reports and health room records of the school nurse. Almost all official accident reports originated with the school nurse, who did not, however, use explicit criteria to decide which accidents were reported and which were not. Implicitly, based on more than 20 years of experience at the study school, the nurse judged (1) whether the pupil needed to be referred for further evaluation and care, and (2) whether the school, specific personnel, or another pupil might be considered liable for the accident. She completed accident reports in any of these cases. Most pupils for whom accident reports were filed were removed from physical education classes until their injury was fully evaluated.

The official accident reports contained the sex, age, and grade of the pupil; type of injury; body part injured; assumed cause of the injury; area of the school and activity in which the injury occurred; course of action taken (ie, referred for care, sent home, returned to class); and results of referral, if known. No explicit criteria were used for categorizing the injury (eg, contusion, sprain, laceration), though the diagnosis of fracture required roentgenographic confirmation. If two injuries were listed (eg, sprain and contusion), the injury considered to be primary (eg, sprain) was used in this study. The activity in which a pupil was engaged was classified according to specific sports and as to whether the injury involved the person only or involved others (eg, collision).

Officially reported accidents represented only a part of all physical education class-related injuries. The school nurse also saw a number of pupils for physical education class injuries that were not recorded on accident reports. Because school policy dictated that a record be kept of the complaint at the time of presentation and disposition of all visits to the nurse for any reason, information about physical education class injuries was available on individual pupil health records. The same injury classification was used in these records as was used in the accident reports. To estimate the number of injuries that were not recorded on official accident reports, health records of all 12th-grader pupils in 1976-1977 school year were examined for notations of physical education class-related injuries. If an injury was noted on both an accident report and on the pupil's health record, it was treated only as an official accident report injury in this study.

RESULTS

Rate and Type of Accident Report Injuries

Between September 1976 and June 1978, there were official school accident reports of 134 injuries related to participation in physical education classes. These injuries occurred during 3,737 pupil years of observation; a rate of 3.6 reported injuries per 100 participants per year. The grade and sex of pupils, type of injury, and rate per 100

Boys	12	0	7	0	12	0	6	0	0	1

*As seen by the school nurse but not noted on school accident reports.

pupil years are given in Table 1.

Overall, rates of reported injuries were approximately equal for boys and girls, although ninth grade girls had almost four times the injury rate of ninth grade boys, and 12th grade boys had approximately twice the injury rate of 12th grade girls. More than half the total injuries noted in accident reports were sprains and about 37% were contusions or abrasions. Fractures, lacerations, and miscellaneous injuries totaled about 10%. The proportions of the various injury categories were similar in both sexes and in all grades. Thirty (22%) of the 134 accident report injuries were referred for medical evaluation and 25 of the 30 (83%) received a roentgenogram to determine presence of a bone fracture. The anatomical locations of accident report injuries are given in Table 2.

Circumstances of Accident Report Injuries

Of the 134 accident report injuries, 97 were individual injuries and 37 occurred in an interaction with another participant. Of the 97 individual injuries, 33 occurred by contact with a ball, two by the pupil running into a volleyball post, one by the pupil hitting himself on the head with a bat, and the remaining 61 involved no specific contact with equipment.

Of 71 sprains, 34 (48%) occurred to the ankle and 17 (24%) to the wrist or fingers. Sixteen sprains (23%) occurred when the pupil was trying to catch or hit a ball (eg, basketball, volleyball, dodgeball), whereas 43 (61%) involved only the injured person (eg, falling). The largest single cause of contusion and abrasion in girls (14 of 30) was being struck by a field hockey stick. Of the four fractures, the two of the foot or ankle were caused by twisting the foot or ankle while in motion, and the two of the fingers were caused by contact with a basketball and by being hit with a field hockey stick.

Basketball was the activity most commonly associated with reported injuries of the ankle or foot (12 of 41). Eleven of these 12 basketball injuries occurred by twisting an ankle when coming down from a rebound. Almost half of the injuries to the wrist and hand were due to contact with a ball and occurred more frequently to girls (26 of 36) than to boys (ten of 36). Eleven of the 29 injuries to the head were caused by a ball, nine by a collision, and five by a field hockey stick.

Characteristics of Health Room Record Reported Injuries

Of the 484 members of the 1976-1977 12th-grade class sampled for injuries noted in the nurse's health room record but for which no accident report was filed, 26 (seven girls and 19 boys) were found to have sustained an injury in physical education class: a rate of 5.4 per 100 pupil years. Table 3 gives type and anatomical location of these injuries.

COMMENT

Three aspects of the physical education class-related injuries observed in this study merit comment: (1) their severity and frequency compared with injuries reported in other studies; (2) the different injury rates of boys and girls; and (3) the likelihood that these injuries could be prevented.

Comparison With Other Studies

The National Center for Education Statistics, based on a survey of 2,500 public and private secondary schools in academic year 1975-1976, reported 90,651 injuries in 4.74 million girls and 138,616 injuries in 4.93 million boys who participated in physical education classes.[2] Although these injuries were not classified by severity, type, or

location, the overall rate of 2.4 injuries per 100 pupil years is similar to that observed in the official accident report injuries in the study reported here (3.6 injuries per 100 pupil years).

This injury rate determined for physical education classes is considerably less than the injury rate determined by Garrick and Requa for competitive interscholastic athletic competitions with practices.[5] They reported two years' experience with interschool sport-related injuries in four Seattle area high schools, and found that 39 per 100 sports participants per year sustained a "medical problem resulting from athletic participation necessitating removal from a practice or competitive event and/or resulting in missing a subsequent practice or competitive event." Although the Pittsburgh pupils with official accident reports were removed from physical education participation until their injury was evaluated, the Pittsburgh and Seattle criteria for injury were not identical. However, the accident report injuries of the Pittsburgh study seem to be of similar severity to those reported in interschool sports in the Seattle study. Forty-two percent of the Seattle and 22% of the Pittsburgh study students were referred for further evaluation and care, and of those referred, 71% of the Seattle and 83% of the Pittsburgh students received roentgenograms. The Pittsburgh and Seattle injury frequency rates (3.6 per 100 physical education class participants per year and 39 per 100 sports participants per year) are not strictly comparable because of differences in hours and intensity of exposure of pupils in physical education classes and in interschool sports. Injury rates of pupils in the Pittsburgh study were calculated on the basis of a maximum of 48 hours per year spent in a variety of physical education class activities. Seattle pupil rates were calculated with respect to participation in specific sports. It is quite certain that the hours of practice and competition spent in any single sport exceeded the annual total time in physical education class (48 hours). Thus, although the Pittsburgh injury rate of 3.6 per 100 physical education class participants per year was less than a tenth of the Seattle sports injury rate calculated on a per season basis, the Pittsburgh and Seattle injury rates might have been closer if both had been based on hours of exposure in individual activities. Other factors, such as intensity of activity and complaint threshold, though difficult to assess, also would affect comparisons of injury rates in the two studies.

The injuries in the Pittsburgh study that were noted only in the nurse's health room record, seem to have been much less severe than those reported in the Seattle and National Center studies. None of these 5.4 injuries per 100 pupils per year was referred for further evaluation or care, and there were no fractures.

Rates in Girls and Boys

In the Pittsburgh study of official accident reports, there was surprisingly little difference when all high school grades were totaled between boys and girls in the frequency and apparent severity of injuries sustained in physical education class activities. Although this observation is in agreement with other reports in which boys and girls have similar injury rates in noncontact sports,[2,6] it does not necessarily follow that injury rates and severity are similar in the two sexes. There was considerable difference in official accident reports between injury rates of boys and girls in the ninth and 12th grades: girls having higher rates in the former and boys in the latter. In nurse's reports of reasons for health room visits of 12th graders, boys also outnumbered girls for physical education-related injuries. A further difficulty in comparing injury rates of boys and girls was noted by Garrick and Requa,[4] who observed that there are differences in boys' and girls' physical activities, even in those with the same names (eg, gymnastics), as well as differences between sexes in sports expertise and possibly in thresholds of tolerance to discomfort.

Prevention

Although the incidence of physical education class-related injuries in the Pittsburgh study was small and their severity mild, the possibility of prevention was considered. Most commonly, the injuries were sustained by falling or tripping, and next most commonly by contact with a ball. Both of these circumstances reflect musculoskeletal skill, conditioning, and experience. Theoretically, body conditioning and skill enhancement might reduce such injuries. It is possible, however, that the low incidence and severity of the injuries sustained in physical education classes might not provide sufficient motivation for the students involved to participate in conditioning programs to reduce such injuries. With the exception of field hockey, where protective equipment for the hands and face would possibly aid in lowering the specific injury rate, no specific set of circumstances was identified that was implicated in more than a few injuries and that was modifiable by protective equipment.

Adolescents participating in physical activity such as that required by high school physical education programs are always at risk for injury. The low incidence and mild severity of physical education class related injuries suggest that they were not a major health problem in the high school that was studied.

Lewis Nettrour, MD, suggested the study reported here.

Inhibition of Iron Absorption From Human Milk by Baby Food

Frank A. Oski, MD, Stephen A. Landaw, MD, PhD

• We measured the effect of a common baby food, strained pears, on the absorption of iron from human milk. Five adult subjects were initially fed 1 dL of human milk that contained added ferrous citrate Fe 59; the same subjects were later fed human milk and one jar of baby food. Incorporation of ^{59}Fe into RBCs averaged approximately one quarter of the administered iron from the human milk. When the milk was combined with the baby food, incorporation was significantly decreased. The addition of a supplemental food to the diet of the breast-fed infant impairs the bioavailability of the iron from human milk.

(*Am J Dis Child* 134:459-460, 1980)

Infants absorb 50% to 70% of the iron present in human milk as contrasted with 10% of the iron in cow's milk and 3% to 5% of the iron in iron-fortified proprietary formulas.[1-4] Infants who are exclusively breast fed for periods of six to nine months maintain normal hemoglobin values and normal iron stores. As early as 1928, Mackay[5] reported that infants who were exclusively breast fed had higher hemoglobin values than artificially fed infants but that this difference began to disappear when the breast-fed infants were offered solid foods. More recent studies have suggested that the preferential iron balance observed in exclusively breast-fed infants is no longer present when these infants receive traditional baby foods.[6,7]

See also p 453.

These observations suggest that the superior bioavailability of iron from human milk is compromised by the presence of other foods in the diet. We report our findings that show a marked inhibition of radioiron absorption from human milk when a typical baby food is added to the test meal fed to normal adults.

SUBJECTS AND METHODS

Human milk was obtained from four lactating women who were breast feeding their infants for periods of three to six months. The human milk was pooled and stored at −20 °C until use.

Five healthy, iron-sufficient men served as subjects. After fasting for eight hours, each subject was fed 1 dL of human milk in the first test period and 1 dL of human milk and one jar (128 g) of strained pears in the second test period. After each feeding, the subjects fasted for an additional four hours.

The interval between the first and second test meal was two weeks. Ten microcuries of ferrous citrate Fe 59 (^{59}Fe) was added to the milk prior to ingestion, and iron absorption studies were performed as previously described.[1] A standard solution of the milk was prepared for analysis by diluting 1 mL of milk with 99 mL of saline.

Fourteen days after the ingestion of the first test meal, blood samples were obtained from each subject just prior to the ingestion of the second test meal and again 14 days after the ingestion of the second test meal. Red blood cell and plasma radioactivity were assessed from duplicate 2.5-mL samples.

The blood volume of each subject was estimated by applying each subject's weight and height to well-established nomograms.[8] The RBC mass was determined by multiplying the hematocrit value of each subject by the blood volume. No correction was made for trapped plasma. The total ^{59}Fe incorporated into RBCs after ingestion of each test meal was determined by the following formula:

RBC volume × (counts per minute [cpm]/mL of RBC) = total cpm incorporated.

The quantity of iron incorporated into RBCs was then calculated by the following method:

μg of elemental iron incorporated = total cpm incorporated × (μg of elemental iron ingested/cpm of ^{59}Fe ingested).

The percentage of ingested ^{59}Fe incorporated from human milk with and without the pears was then compared by the paired Student's t test.

P value	< .01		< .01	

RESULTS

The mean RBC incorporation of ^{59}Fe from human milk was 23.7% of the administered dose in the first feeding as contrasted with only 5.7% in the second feeding, which included both human milk and strained pears (Table). In all five subjects, an inhibition of iron incorporation was observed when they were fed pears; the mean inhibition was 76% (range, 64% to 87%).

The iron content of the human milk used in this study was 0.76 mg/L. The iron content of the pears was 0.06 mg per jar. According to these figures, the subjects incorporated an average of 0.0178 mg of iron from the first meal as compared with an average of 0.0078 mg of iron from the second meal.

COMMENT

Layrisse and co-workers[9] have demonstrated that exogenous iron added to ingested food is absorbed at the same rate as the endogenous iron in the food. Taking advantage of this observation, we have previously shown that approximately 20% of the radioiron added to a test meal of human milk is incorporated into the erythrocytes of normal adults.[1,2] The findings in this study are in agreement with those previously reported. The iron incorporated into erythrocytes is estimated to be only 80% of the actual iron absorbed in a test feeding.[8] Infants normally absorb two to five times as much iron from a given food source as do normal adults.[4,10] Saarinen and associates[3] used the method of counting total-body iron after the administration of a tracer dose of iron and found that normal, term infants of approximately 6 months of age absorbed 49% of the iron in human milk. The factor or factors in human milk that are responsible for this enhanced iron absorption are presently unknown.[2] This enhanced bioavailability does not appear to be a consequence of the presence of lactoferrin in human milk.

Saarinen and Siimes[6] estimated the changes in total-body iron content during the growth of infants fed three different milk regimens. The total-body iron was calculated as the sum of the hemoglobin iron and the body-storage iron as reflected by the serum ferritin concentration. The calculated percentage absorption of iron in infants who were exclusively breast fed was estimated to be 70%. After 4 months of age, when solid foods were introduced into the diet of the breast-fed infants, the monthly increments in total-body iron became much smaller. The authors hypothesized that fruits and vegetables produced an inhibitory effect on the absorption of iron from human milk, and they recommended that the introduction of vegetables and fruits be delayed in infants who are being breast fed.

Pears were selected for our study because they are commonly recommended as one member of the fruit group to be used to initiate the feeding of solid foods. Despite the fact that a jar of pears contains 11 mg of ascorbic acid, a facilitator of iron absorption, the pears inhibited iron absorption. The basis for this inhibition is unknown.

The finding that one commonly used infant food markedly inhibits iron absorption from human milk may help to explain why some investigators have failed to demonstrate a superior nutritional state for iron in breast-fed infants.[7] In most comparisons, the breast-fed infants were also being fed solid foods by 3 to 6 months of age.

Pat Viele and the Syracuse, NY, La Leche League helped in this study. Susan Rathbun provided technical assistance.

Salicylate Therapy in Juvenile Rheumatoid Arthritis

Dose, Serum Level, and Toxicity

Robert A. Doughty, MD, PhD; Linda Giesecke, RN; Balu Athreya, MD

• In a prospective study of aspirin therapy for 67 children with juvenile rheumatoid arthritis, we have found that (1) doses greater than 100 mg/kg/day of aspirin may be necessary to achieve therapeutic salicylate levels greater than 20 mg/dL; (2) no improvement in clinical remission rate is seen at salicylate levels greater than 30 mg/dL; (3) clinical toxicity to aspirin is of relatively low incidence (16%), and infrequently causes serious morbidity; (4) symptomatic SGOT elevations are common in the first three months after onset of therapy; and (5) these elevated SGOT levels generally return to normal despite continuation of therapy.

(*Am J Dis Child* 134:461-463, 1980)

Recent publicity about potential toxic effects of aspirin has caused great concern among many parents of patients receiving long-term aspirin therapy for juvenile rheumatoid arthritis (JRA). There is also controversy among pediatric rheumatologists about the risks of using high doses (>100 mg/kg/day) of aspirin[1-3] and concern about the incidence of aspirin-induced hepatotoxic effects.[3-5]

These concerns have resulted in many children with JRA being either started on, or switched to, a regimen of newer nonsteroidal anti-inflammatory drugs before an adequate trial of aspirin therapy has been undertaken. Many of these new drugs have not yet been adequately tested in children, and their efficacy and incidence of side effects are not known. Furthermore, most of these drugs are considerably more expensive than aspirin. To better define the therapeutic dosage and toxic effects of aspirin, we undertook a prospective study of patients with JRA in the Pediatric Rheumatology Clinic of the Children's Hospital of Philadelphia.

Reprint requests to Children's Hospital of Philadelphia, 34th St and Civic Center Blvd, Philadelphia, PA 19104 (Dr Doughty).

The study was designed to answer several questions: (1) What is the dosage of aspirin necessary to obtain a clinical response? (2) What is the incidence of clinical toxic reactions? (3) How do serum salicylate levels correlate with the dosage of aspirin, the clinical response, and evidence of clinical or biochemical toxicity? Patients qualified for the study if they met the preliminary criteria for JRA as defined by the JRA Criteria Subcommittee of the Arthritis and Rheumatism Association.[6]

SUBJECTS AND METHODS

Children were given aspirin in four divided doses. The total daily dosage was calculated to be 100 mg/kg/day for children who weighed up to 25 kg. For children weighing more than 25 kg, the starting dosage of aspirin was 2.4 to 3.6 g/day. Serum salicylate levels (drawn two hours after a morning dose of aspirin) were obtained seven to 14 days after start of therapy. The aspirin dosage was increased gradually or decreased as necessary in attempts to obtain salicylate levels between 20 and 30 mg/dL. In patients with poor clinical responses to aspirin, the dosage was increased to obtain levels as great as 35 mg/dL. A rheumatology nurse-practitioner carefully explained the administration of aspirin and symptoms of toxicity to each patient and the patient's parents.

Frequent home telephone contact was made to promote compliance and closely monitor toxic reactions. After stabilization, salicylate levels were followed up routinely every three months. The SGOT levels were obtained simultaneously with salicylate levels since they have been shown to be sensitive indicators of aspirin-induced hepatotoxic effects.[7]

A complete standardized history and physical examination were obtained for the patient at each visit to judge clinical response to the aspirin. All patients were examined by one of two staff pediatric rheumatologists. Global assessment of clinical responses was graded in three categories: (1) remission, which was the absence of clinical evidence of active joint disease; (2) partial response, which represented those patients demonstrating improvements from their previous examinations; and (3) no response, which consisted of those patients who showed no change in their assessments or worsening of their conditions. Global assessments were based on the following criteria: duration of morning stiffness, functional level, parent-patient self-assessment, and an articular index.

Total serum salicylate levels were measured by the quantitative colorimetric assay of Trinder.[8] The SGOT values were determined by standard laboratory procedure. Normal SGOT values in our laboratory are in the range of 0 to 40 IU. Statistical analyses of data were performed using χ^2 analysis with the Yates correction and the Student's t test.[9]

RESULTS

Our patient population consisted of 67 patients followed up for a mean period of 14.7 months. Children ranged in age from 10 months to 18 years. Of these patients, 17 (25%) had the systemic-type of JRA; 17 (25%) had the polyarticular-type; and 33 (50%) had the pauciarticular-type. Thus, our study population had a slight excess of patients with pauciarticular disease.[10,11]

The average serum salicylate level of each patient during the period of study was calculated and correlated

with clinical response. Twelve patients whose salicylate levels varied widely (> 15 mg/dL) because of poor compliance or perhaps other factors such as altered disposition (absorption, metabolism, or excretion) of aspirin were excluded from the study. In most cases (45/67, or > 70%), salicylate levels for individual patients varied by < 10 mg/dL for any given aspirin dosage. The global assessment of patient responses compared with average serum salicylate levels is shown in Fig 1. It shows a significantly improved response for those patients with salicylate levels greater than 20 mg/dL ($P < .001$). The rate of response was no better for patients with levels greater than 30 mg/dL.

Comparison of global assessment of response with aspirin dosage is shown in Fig 2. There was no significant difference in response rates relative to the aspirin dosage used. Sixteen of our 56 patients who tolerated aspirin therapy (ie, aspirin use was discontinued for 11 patients) were treated with dosages greater than 100 mg/kg/day to obtain therapeutic salicylate levels. Thus, in almost 30% of our patients, dosages in excess of 100 mg/kg/day were required to maintain salicylate levels greater than 20 mg/dL.

Eleven of the children had toxic reactions requiring withdrawal of aspirin therapy. The nature of the toxic reactions and the clinical subgroups of JRA of these children is given in the Table.

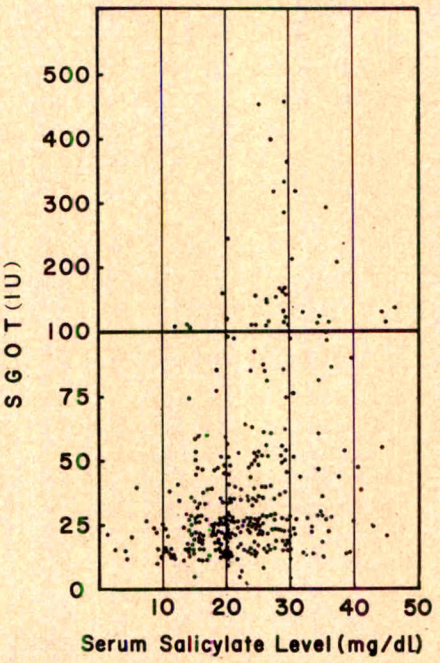

Fig 3.—The SGOT vs serum salicylate levels for juvenile rheumatoid arthritis.

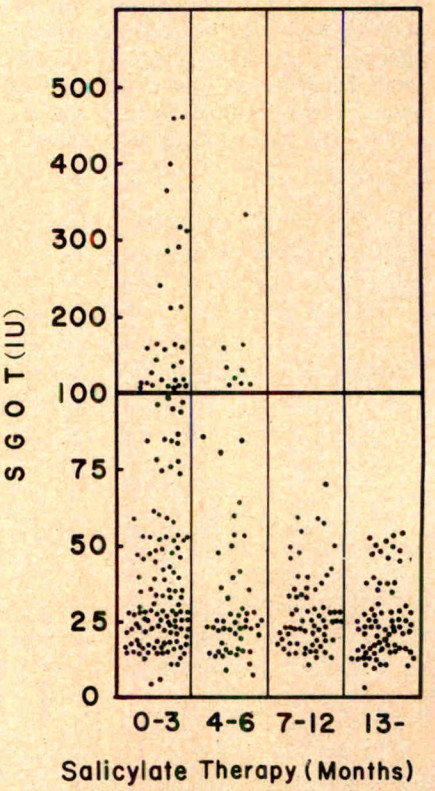

Fig 4.—The SGOT elevation vs duration of aspirin therapy for juvenile rheumatoid arthritis.

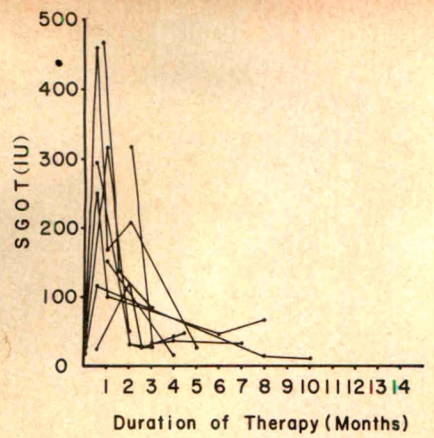

Fig 5.—Serial SGOT elevations for nine newly diagnosed cases of juvenile rheumatoid arthritis treated with aspirin.

Hepatotoxic effects, manifested by modest SGOT elevations (< 400 IU), were frequently seen within one month after the start of therapy. However, most of these patients showed no clinical evidence of hepatitis; occasionally they would complain of nonspecific abdominal pain without other evidence of hepatitis from results of either history or physical examination. In most of these patients (15 of 18), SGOT values returned to normal in the initial three months of therapy. To further investigate these aspirin-induced hepatotoxic effects, serum salicylate levels were compared with simultaneous SGOT determinations for 93 patients (our original group of 56, plus 37 patients whose conditions were diagnosed after discontinuation of the study). Figure 3 is a scattergram of 340 simultaneous salicylate levels and SGOT determinations in these 93 patients. As previously demonstrated by others, it shows that, in patients with JRA, there is a positive correlation between the salicylate level and the SGOT elevation.[4,7,12]

Figure 4 shows SGOT values correlated with duration of therapy for 93 patients. Substantial decreases in the SGOT values within the first three months of therapy are noted. Those five patients with symptomatic hepatitis for whom aspirin therapy was discontinued are excluded from this graph. In Fig 5, serial SGOT values are shown for nine patients in whom salicylate levels were within the therapeutic range. This shows a similar pattern of decrease in SGOT values over time.

COMMENT

Our study showed that serum salicylate levels greater than 20 mg/dL correlated well with improved clinical response. Although this serum level is frequently used as a therapeutic level,[3] its efficacy is not well documented in the literature. No substantial improvement in clinical response was seen at salicylate levels greater than 30 mg/dL. Our subjective opinion that certain patients seem to do better at salicylate levels greater than 30 mg/dL was not demonstrated in this study; however, this possibility may be masked by the fact that some patients in the "greater than 30 mg/dL" group who are in the remission or partial-responder groups may have had their aspirin dosages increased because of partial or poor responses at lower salicylate levels. Thus, there may be a subgroup that requires higher salicylate levels for good clinical response.

Sixteen patients (28%) required aspirin dosages in excess of 100 mg/kg/day to obtain consistent salicylate levels greater than 20 mg/dL. There was no increased incidence of clinical toxic effects seen in these patients. The concern expressed by other authors about clinical toxic reactions resulting from use of aspirin dosages greater than 100 mg/kg/day[1] was not supported by our study.

In contrast to the opinions of others,[7-13] our study did not demonstrate that aspirin toxicity was more frequent in patients with the systemic form of JRA than in those with the polyarticular form. However, there were significantly fewer patients with pauciarticular disease in whom it was necessary to discontinue aspirin therapy because of hepatotoxic effects ($P < .025$).

Patients with symptomatic hepatotoxic effects had vomiting, liver tenderness, and hepatomegaly. All showed marked elevations in SGOT levels (frequently > 1,000 IU), and some had prolongation of the prothrombin time.

It is interesting that five of the 11 patients with symptoms of aspirin toxicity were subsequently given salicylate choline as alternative therapy and successfully treated (obtaining serum salicylate levels in the therapeutic range of 20 to 30 mg/dL) without recurrence of toxic symptoms. Thus, to summarize the clinical toxic data, aspirin was relatively well tolerated in our patients and there were no serious toxic effects such as overt gastrointestinal hemorrhage or peptic ulcer. Therapy with the drug was discontinued in 16% of our patients. Ninety-one percent of the group tolerated either aspirin or salicylate choline as the sole anti-inflammatory agent.

CONCLUSION

We believe this study supports the contention that aspirin, even in high doses, remains a safe and effective agent for treatment of JRA. Because of its effectiveness, low incidence of toxic effects, and low cost, an adequate trial of aspirin should generally be attempted before resorting to other nonsteroidal anti-inflammatory drugs.

Coarctation of the Aorta in Children

Late Results After Surgery

Lee B. Beerman, MD; William H. Neches, MD; Roger E. Patnode, MD; Frederick J. Fricker, MD; Robert A. Mathews, MD; Sang C. Park, MD

• From 1960 to 1970, 110 patients underwent operation for coarctation of the aorta. The overall mortality was 23%. However, in infants operated on at less than 6 months of age, the mortality was 63%, whereas there was only a 4% mortality in those operated on after 6 months of age. Late follow-up was available in 87 patients from five to 15 years postoperatively. There was a 14% frequency of recoarctation in the group of long-term survivors. Systemic hypertension, defined as an upper extremity blood pressure greater than 140/90 mm Hg, was found in 23% of the survivors. This study has demonstrated a significant frequency of postcoarctectomy hypertension and residual hemodynamic and angiographic abnormalities in patients without clinical evidence of recoarctation. This indicates the need for continued long-term follow-up of these patients.

(*Am J Dis Child* 134:464-466, 1980)

Successful surgical correction of coarctation of the aorta (COA) has been carried out since 1939. Several studies evaluating the long-term results after operation have demonstrated substantial residual cardiovascular abnormalities.[1-3] These residua include persistent or recurrent stenosis of the original coarctation, hypertension, and premature cardiovascular death. The etiology of the persistent hypertension is uncertain as it can be related to recoarctation in less than approximately one third of the cases.[2] This report reviews the immediate and long-term results of surgery in a series of patients who underwent operation for COA at Children's Hospital of Pittsburgh.

SUBJECTS AND METHODS

In the period from 1960 to 1970, 110 patients underwent surgical correction of COA, present either as an isolated defect or associated with a patent ductus arteriosus or a ventricular septal defect (VSD). However, patients with aortic or mitral valve abnormalities were included if these lesions did not influence the initial management of their conditions. Patients with COA associated with complex congenital heart disease such as conotruncal abnormalities or valvular atresias were not included. All inpatient and outpatient records were reviewed, as were data from postsurgical cardiac catheterizations when available. Patients were grouped according to age at operation, and the immediate and late results of surgery were tabulated.

Late follow-up was available for 87 patients from five to 15 years postoperatively. Cardiac catheterization was performed on 22 long-term survivors because of either clinical evidence of recoarctation (12 patients) or associated cardiac anomalies (ten patients). These 22 patients were also grouped according to age at operation, and the results concerning the frequency of hypertension and recoarctation as well as angiographic and hemodynamic data were analyzed.

Significant hypertension was arbitrarily defined as blood pressure (BP) of greater than 140/90 mm Hg obtained in the sitting position on repeated determinations. Patients were considered to have the clinical findings of recoarctation when they had a systolic BP differential between the upper and lower extremities that was greater than 20 mm Hg. As this study was retrospective, we chose to use these rigid criteria for significant hypertension and recoarctation so that patients with borderline values would not falsely increase the frequency. The term recoarctation has been used in this study since it is impossible to determine whether a postoperative BP gradient is due to residual or recurrent coarctation.

RESULTS

Of the 110 patients included in this study, the overall mortality was 23%. Of the 25 deaths, 19 occurred within one month of the operation and were considered early deaths. There was a striking relationship between mortality and age at operation (Table 1). Of the 35 patients, 22 (63%) who underwent surgery at less than 6 months of age died, whereas the mortality for those more than 6 months of age was

*Systolic gradient is greater than 20 mm Hg.
†One patient has renal disease as well.

4%. All but one of the early deaths occurred in children less than 6 months of age who frequently had associated intracardiac lesions such as a VSD. There were six late deaths (ie, those occurring more than one month postoperatively). Three died in infancy from congestive heart failure with or without superimposed pneumonia, and a fourth infant died during operation for mitral stenosis. One child died during operation for a VSD and another child died of subacute bacterial endocarditis on a mildly stenotic bicuspid valve.

Twelve of the 87 patients (14%) with long-term follow-up, from five to 15 years postoperatively, had clinical evidence of recoarctation. In each case, cardiac catheterization demonstrated a systolic gradient (<20 mm Hg) across the coarcted segment. The relationship between the frequency of recoarctation and age at operation is given in Table 2. Although only 32% of all the patients studied were less than 6 months of age at the time of operation, 50% (six of 12) of those who had recoarctation develop were in this age category.

Systemic hypertension was found in 20 of the 87 (23%) long-term survivors. The relationship between hypertension, recoarctation, and age at operation is depicted in Table 3. Seven of the 20 hypertensive patients had recoarctation to explain their elevated BP (one of these also had renal disease). The frequency of persistent hypertension increased with the age at operation. Four of 28 patients (14%) younger than 6 years of age at operation had persistent hypertension, whereas 16 of 59 patients (27%) older than 6 years of age at operation had hypertension at follow-up. Of note is the fact that all four of those in the younger age group had recoarctation as an explanation for their hypertension, whereas only three of 16 (19%) of the hypertensive older children had residual aortic narrowing. The frequency of postoperative hypertension for patients in the older age group at the time of operation was unrelated to the duration of follow-up.

Cardiac catheterization data for 22 of the long-term survivors were analyzed. Twelve of these patients were catheterized because of clinical evidence of recoarctation and all 12 were found to have residual systolic gradients greater than 20 mm Hg. Of these 12 patients, six were hypertensive (BP >140/90 mm Hg).

Of the ten patients not considered to have recoarctation clinically, seven had persistent systolic gradients (three <10 mm Hg, four from 10 to 20 mm Hg) and angiographic evidence of some narrowing at the site of the previous coarctation repair. The other three patients had no systolic gradient. None of these ten patients showed signs of hypertension.

COMMENT

The overall mortality in this series was 23%, and this was definitely related to surgery performed on infants less than 6 months of age, often with associated intracardiac lesions (early mortality in this age group was 50%). In the last five years, with improvements in operative techniques, postoperative care, and the trend toward early operation on sick infants, the mortality in this age group in our institution has been reduced to less than 20% and occurs mainly in infants less than 1 month of age. The majority of these sick infants have an associated VSD. This combination of pressure and volume overload leads to the early appearance of congestive heart failure. The conditions of these infants have been successfully managed by coarctectomy alone, at our institution.[4] In most instances, the VSD does not necessitate any additional surgical intervention in infancy.

Previous studies have demonstrated that even though there has been

almost 40 years of experience with surgical correction of coarctation of the aorta, there are important cardiovascular abnormalities at long-term postoperative follow-up. Maron et al[1] reported that there was a 12% frequency of premature cardiovascular-related deaths (ie, ruptured major arterial vessel, congestive failure, or early arteriosclerotic vascular disease) in patients after coarctectomy. The mean age of death in that series was 34 years, which, interestingly, was the average life span prior to the surgical era.[1] In addition, persistent hypertension was found in 34% of their postoperative patients. In a review by Nanton and Olley[2] of the experience at Toronto Hospital for Sick Children, 24% of patients remained hypertensive after operation. This hypertension could be related to recoarctation or some other definite cause (ie, renal disease or aortic insufficiency) in only approximately one third of the cases. In this series, there was an 11% frequency of recoarctation.

The review of our experience at Children's Hospital of Pittsburgh confirms the significant incidence of hypertension at long-term follow-up. The overall frequency was 23%; however, it was somewhat more common in children who were operated on after the age of 6 years (27% vs 14% in those <6 years of age). Although varying methodologies and lack of agreed-on criteria for defining hypertension in children and adolescents have led to considerable variation in estimates of its frequency in a normal population, recent studies have indicated a maximum frequency of hypertension between 2.5% and 12.2% in this age group.[5] Therefore, it is clear that hypertension is found much more often in patients who have had coarctectomy than in the general population.

Recoarctation occurred in an overall frequency of 12%, but it was much more common in those operated on during the first 6 months of life. Persistent hypertension in children operated on before 6 years of age could be related to recoarctation in every case, whereas the elevated BP was largely unexplained in the older age group (only four of 16 had recoarctation). This suggests that persistent hypertension in children without clinical evidence of recoarctation may be related to prolonged preoperative hypertension and the subsequent development of structural or functional vascular changes. However, it is possible that patients operated on at younger ages may subsequently have a similar incidence of hypertension develop when followed up for longer periods of time.

Several studies have documented the increased frequency of exercise-induced hypertension in patients who have had previous operations for COA.[6,7] A recent report by Freed and co-workers[8] concluded that this abnormal response to exercise after coarctectomy may be due to mild but important recoarctation that was not predicted by the low resting gradient between upper and lower extremity BPs. This conclusion is supported by the rather high incidence of residual hemodynamic and angiographic abnormalities in patients without clinical evidence of important recoarctation found in our study.

Newer surgical techniques such as the subclavian patch procedure may reduce the incidence of recoarctation. However, more experience and longer follow-up will be necessary before the relative merits of these techniques can be evaluated.

Postoperative evaluation of patients who have had repair of COA should include careful documentation of BP in the lower extremities (as well as upper) in both the resting state and during exercise testing. In view of the substantial postoperative cardiovascular residua (especially hypertension and recoarctation) amply documented by this study and others in the literature, careful long-term follow-up of these patients as well as elimination of other cardiovascular disease risk factors is necessary.

James R. Zuberbuhler, MD, and Cora C. Lenox, MD, helped in the preparation of this manuscript. They also devoted time to the clinical care of these patients. Beverly Collins provided technical assistance.

Transient 'Lazy-Leukocyte' Syndrome During Infancy

Satoru Yoda, MD; Hironori Morosawa, MD; Atsushi Komiyama, MD, PhD; Taro Akabane, MD, PhD

• A male infant with transient severe neutropenia and defective neutrophilic mobility is described. He had recurrent upper respiratory infections that responded well to antibiotics. The neutrophilic counts continued to be less than 300/cu mm, and neutrophilic random mobility and chemotaxis were persistently defective during early infancy but were normal at 16 months of age. No ultrastructural abnormality was found in the neutrophils. Phagocytic and bactericidal abilities of the cells were not impaired. Bone marrow was normal. The clinical and laboratory findings suggest that this disorder is transient "lazy-leukocyte" syndrome.

(*Am J Dis Child* 134:467-469, 1980)

In recent years, much attention has been paid to the relationship between neutropenia and defective neutrophilic mobility in patients with recurrent pyogenic infections.[1,2] We describe a male infant in whom severe neutropenia and defective neutrophilic mobility were persistently present during early infancy and in whom their spontaneous normalization occurred at 16 months of age. To our knowledge, such a patient has as yet not been reported and the disorder seems to be transient "lazy-leukocyte" syndrome.

REPORT OF A CASE

An 8-month-old male infant came to our clinic in October 1977 with a history of recurrent infections. He was born at term after a normal pregnancy. He was in good health until 4 months of age when he visited another hospital for tonsillitis and was first discovered to be severely neutropenic. During the next four-month period, during which he was followed up at the hospital, he had recurrent tonsillitis that responded well to antibiotics and he had persistent neutropenia (neutrophils were less than 300/cu mm). He had stomatitis twice but no pyogenic infections except tonsillitis. Family history was unremarkable.

Physical examination showed a well-developed infant. The liver was palpable 2 cm below the right costal margin. There was no enlargement of the spleen and lymph nodes. He had no eczema.

Hemoglobin concentration was 12.1 g/dL; platelet count, 178 × 10^3/cu mm; and leukocyte count, 10,200/cu mm, with 2% neutrophils, 4% eosinophils, 1% basophils, 86% lymphocytes, and 7% monocytes. Bone marrow was normocellular and showed a myeloid-erythroid ratio of 3:1. Differential cell count indicated 2.8% myeloblasts (normal range, 0.2% to 5.0%), 8.0% promyelocytes (0.5% to 10.0%), 6.6% myelocytes (5.0% to 15.0%), 7.0% metamyelocytes (5.0% to 15.0%), 17.4% band forms (5.0% to 20.0%), and 5.3% fully matured segmented neutrophils (1.0% to 15.0%). Serum immunoglobulin concentrations were as follows: IgG, 1,572 mg/dL; IgA, 48 mg/dL; IgM, 130 mg/dL; IgD, 0 mg/dL; and IgE, 7 units/mL. Serum complement levels were: C3, 128 mg/dL; and C5, 7.8 mg/dL. Circulating T (51%) and B (30%) lymphocytes were normal in number as estimated by rosette formation with sheep erythrocytes and with those coated with specific antibody and complement, respectively.

Tritiated-thymidine uptake by peripheral lymphocytes was normal after phytohemagglutinin, concanavalin A, or pokeweed-mitogen stimulation. Delayed hypersensitivity response to *Candida*, streptokinase-streptodornase, or purified protein derivative was negative, and that to phytohemagglutinin was positive.

At 10 months of age, the patient started to receive ascorbic acid therapy (200 mg daily), with no clinical and hematologic improvements. During the next five months, he experienced stomatitis, tonsillitis, or bronchitis on several occasions, and neutropenia persisted. At 15½ months of age, the dosage of ascorbic acid was increased to 400 mg daily. Two weeks later, the neutrophilic counts increased to normal range and have remained at normal levels until the latest examination, at 24 months of age, although the ascorbic acid dosage

Serial neutrophilic counts and ascorbic acid administration.

was decreased to 200 mg daily at 17 months and was discontinued at 20 months of age (Fig 1).

MATERIALS AND METHODS

All studies except peripheral neutrophilic counts were performed when the patient was free of infection. Peripheral neutrophilic counts were studied at intervals from three days to one month during the observation period. For studies of neutrophilic morphology and functions, heparinized peripheral blood was obtained from the patient and from several control patients in whom neither hematologic nor immunologic abnormalities were found. Neutrophilic suspension was prepared as previously reported.[3] Electron microscopy of neutrophils was carried out as described elsewhere.[3] In brief, neutrophils were fixed with 2.5% glutaraldehyde fixation and 1% osmium tetroxide fixation, and they were routinely processed for electron microscopy. Epinephrine hydrochloride and hydrocortisone sodium succinate stimulation tests were routinely done: epinephrine hydrochloride (1:1,000), 0.2 mL, was given intravenously, and hydrocortisone sodium succinate, 4 mg/kg, intravenously. Leukocyte migration in vivo was measured by the method of Rebuck and Crowley.[4] Random mobility was studied in vitro by the capillary tube method[5] and by the filter technique using a membrane filter, 8 μ in pore size, and a Boyden chamber. In vitro chemotaxis was examined by a modification of Boyden's method using a membrane filter, 3 μ in pore size. Culture filtrate of *Escherichia coli* was used as a chemotactic factor. Incubation time was four hours for capillary tube migration assay, and it was three hours for random filter mobility and chemotactic assays. Random tube mobility was measured by migration distance. To evaluate random filter mobility or chemotaxis, the index was calculated by dividing the number of neutrophils in ten fields of finished side by that of starting side (×1,000). Random mobility and chemotaxis were studied four times. Nitro blue tetrazolium dye (NBT) reaction was done according to the method of Park et al.[6] Phagocytic and bactericidal abilities against *Staphylococcus aureus* were estimated by the method of Tan et al.[7]

RESULTS

As described earlier, the absolute neutrophilic counts continued to be less than 300/cu mm until 15½ months of age. At 16 months of age, the neutrophilic counts increased to normal range and they have remained at the normal range thereafter (Fig 1). No structural abnormality of neutrophils was found on either light or electron microscopy. The response to epinephrine was poor: epinephrine stimulation increased the absolute neutrophilic count from 288/cu mm to 1,200/cu mm, which was less than the lowest limit of normal response of 2,200/cu mm.[8] The hydrocortisone administration increased the absolute neutrophilic count from 107/cu mm to 696/cu mm. The in vivo leukocyte migration study by Rebuck and Crowley[4] showed migration of only a few neutrophils. Migration of mononuclear cells was normal. Results of neutrophilic random mobility and chemotaxis are given in the Table. When studied at 8, 10, and 11 months of age, random tube migration of the patient's neutrophils in each study was impaired: values of migration distance of the patient's cells were between 6.2 and 7.5 mm as compared with that of control cells of 15.0 ± 1.0 mm. The random filter mobility index of the patient's neutrophils was 86 at 8 months of age, which was only 23% of that of control cells (380 ± 30). In control children, the neutrophilic chemotactic index was relatively constant when the cell suspension was prepared at concentrations of 5×10^5 to 2×10^6 cells per milliliter. The cell concentration was adjusted, therefore, to be 5×10^5 cells per milliliter in every experiment of the present chemotactic study. The patient's chemotaxis was defective during infancy: the patient's values were between 90 and 161 cells per milliliter as compared with the control value of

409 ± 84. When studied at 16 months of age, the random migration and chemotaxis were normal. The NBT test result was normal. The phagocytic and bactericidal abilities were normal.

COMMENT

Our patient had recurrent tonsillitis and stomatitis, but he had no severe pyogenic infection. Severe neutropenia and defective neurophilic mobility were observed during infancy, and they were found to be normal when he was 16 months of age. Neutrophils were normal in structure. Bone marrow examination showed a normal number of mature neutrophils. Stimulation with epinephrine or hydrocortisone increased the neutrophilic counts, but peak increases were lower as compared with normal values.

In 1971, Miller and co-workers[1] described two cases of "lazy-leukocyte" syndrome, and in 1975, Constantopoulos et al[2] reported another case. The "lazy-leukocyte" syndrome is characterized by recurrent infections, severe neutropenia, normal bone marrow reserve, and defective neutrophilic random mobility and chemotaxis. In the disorder, neutrophilic response on stimulation with epinephrine or hydrocortisone is poor. The clinical and laboratory features of "lazy-leukocyte" syndrome appear identical to those of our patient during infancy. Initially, therefore, the diagnosis of "lazy-leukocyte" syndrome was made.

It is of interest that the neutropenia and defective neutrophilic mobility were improved at 16 months of age in our patient. In recent years, ascorbic acid has been demonstrated to improve neutrophilic functions[9] including neutrophilic mobility. Our patient was treated with ascorbic acid, and the neutrophilic count and mobility were improved after an increase of its dosage from 200 mg to 400 mg daily. It is unlikely, however, that the improvement in neutrophilic count and function is directly due to ascorbic acid because a decrease in dosage and even discontinuation of the drug did not reduce the cell count.

Spontaneous recovery from neutropenia has been demonstrated in several patients with chronic benign neutropenia.[10-12] Salmonssen[10] described a patient with neutropenia and episodes of catarrhal infection, mouth ulcer, and stomatitis. The disease was self-limited, beginning at 2½ years of age. Similar cases were also reported by other.[11,12] In chronic benign neutropenia, bone marrow is normal or lacks fully matured neutrophils.[11] In the disorder, unfortunately, the detailed studies are lacking in the functions of neutrophilic mobility.[12] For our patient, therefore, the diagnosis of chronic benign neutropenia might be made on the basis of the benign clinical course, transient neutropenia, and normal marrow, unless neutrophilic functions were studied.

Because of lack of studies on "lazy-leukocyte" syndrome for a period of years and the lack of neutrophilic function studies on chronic benign neutropenia, the difference between the two disorders is still obscure. The present report demonstrates a case in which not only the neutrophilic count but also its mobility underwent spontaneous normalization and further suggests that the disorder is transient "lazy-leukocyte" syndrome during infancy.

Phenotypic Variation in a Family With Partial Androgen Insensitivity Syndrome

Marc Maes, MD; Peter A. Lee, PhD, MD; Robert D. Jeffs, MD; Charles Sultan, MD; Claude J. Migeon, MD

• **A family with partial androgen insensitivity syndrome exhibited considerable variation in phenotypic expression of their androgen resistance. One subject died at 2½ years of age of a Wilms' tumor. In the two living members, one had a micropenis with otherwise normal genitalia, while the other had a small phallus, perineoscrotal hypospadias, bifid scrotum, and persistence of a vaginoutricular pouch. At puberty, plasma androgens and serum gonadotropins increased to normal or elevated values. However, despite adequate endogenous plasma testosterone levels and testosterone therapy, these patients showed poor virilization and were sterile. Studies of cultured sexual skin fibroblasts showed adequate 5α-reductase activity and normal receptor affinity and capacity for dihydrotestosterone. An X-linked mode of inheritance is postulated, although autosomal dominance cannot be ruled out.**

(*Am J Dis Child* 134:470-473, 1980)

Among the variety of disorders leading to male pseudohermaphroditism, end-organ resistance to androgens has been characterized in detail. In 5α-reductase deficiency, absence of the intracellular enzyme that converts testosterone to dihydrotestosterone (DHT) is believed to be the cause of androgen resistance.[1,2] We have recently reported that complete androgen insensitivity syndrome (CAIS), or testicular feminization, was due to the absence of androgen receptor activity in sexual skin fibroblasts.[3] However, some subjects with CAIS have normal receptor activity, and it has been postulated that their androgen resistance is due to an abnormality of the binding of the DHT-receptor complex to the specific acceptor site on chromatin.[4] In some patients with partial androgen insensitivity syndrome (PAIS), the degree of DHT binding in cultured skin fibroblasts is definitely below normal values but not completely absent.[5,6] However, other subjects with PAIS have perfectly normal DHT binding.[6,7] Clinically, patients with PAIS have variable phenotypic expression of their androgen resistance ranging from severe pseudohermaphroditism to normal phenotypes with defective spermatogenesis as reported by Bowen et al,[8] Wilson et al,[9] and Aiman et al.[10]

In the present study, we describe a family with PAIS in whom the three affected members showed different clinical manifestations of their androgen resistance. Furthermore, one patient had a Wilms' tumor. Studies of their plasma androgen and serum gonadotropin levels, testosterone metabolism, and binding by skin fibroblasts are reported along with their response to testosterone therapy.

METHODS

Plasma levels of testosterone,[11] androstenedione,[6] progesterone, 17α-hydroxyprogesterone,[12] serum luteinizing hormone (LH),[13] and follicle-stimulating hormone (FSH)[14] were measured by radioimmunoassay as previously described. The fibroblast culture procedure and the DHT receptor and 5α-reductase assays were reported previously.[6]

REPORT OF CASES

The pedigree of the family is shown in Fig 1.

Case 1.—The case of the maternal "aunt" of the proband (III-3) was evaluated elsewhere. This patient (II-9) was reared as a female because the external genitalia appeared female except for posterior fusion of the labia and the presence of a urogenital sinus. The patient died at 2½ years of age of a Wilms' tumor located in the right kidney. At an autopsy at District of Columbia General Hospital, Washington, DC, metastases were found to extend to the pleura, peritoneum, and pelvis. A mass in the left labia majora was found to be a testis with vas deferens. On microscopic examination, the testis appeared immature. No Barr chromatin bodies were observed in any of the tissues examined, including the two kidneys, Wilms' tumor, and pancreas. There was no evidence of a right gonad, and no genital ducts could be identified.

Case 2.—The patient (III-3) was a 3.230 kg, full-term infant. The pregnancy and delivery were normal. At delivery, he was noted to have a small penis and was reared as a male. At age 3 years, the family physician was concerned about the development of the patient's penis, and a urologic investigation was arranged. The results of a cystoscopic examination, an intravenous pyelogram (IVP), and a testicular biopsy were normal. The results of a buccal smear were negative for Barr chromatin bodies, and his karotype was 46, XY.

At age 3 years 8 months, he was referred to The Johns Hopkins Hospital, Baltimore, for possible treatment of his micropenis. His physical examination, including height and weight, was normal except for a bilateral varus foot deformity and a small penis that measured 2 cm in length when stretched (Fig 2). The urethral opening was normally located at the tip of the penis, and the testes were in the scrotum, which

Accepted for publication Aug 4, 1979.

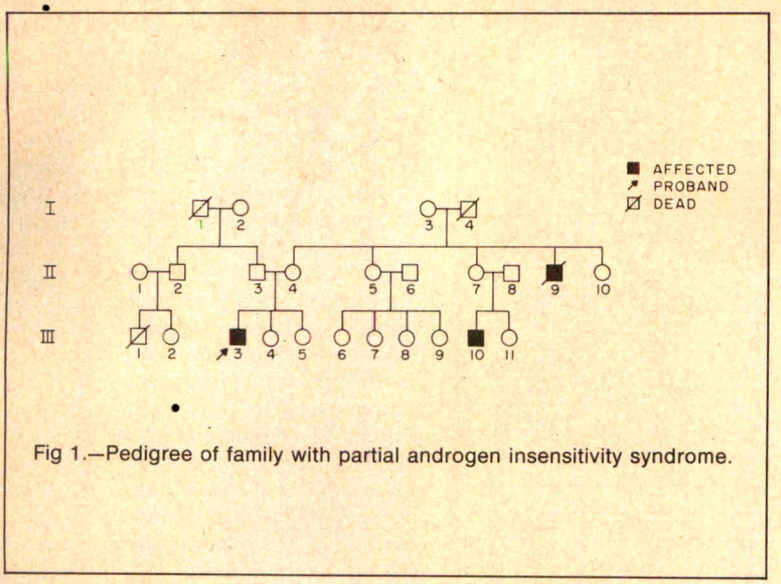

Fig 1.—Pedigree of family with partial androgen insensitivity syndrome.

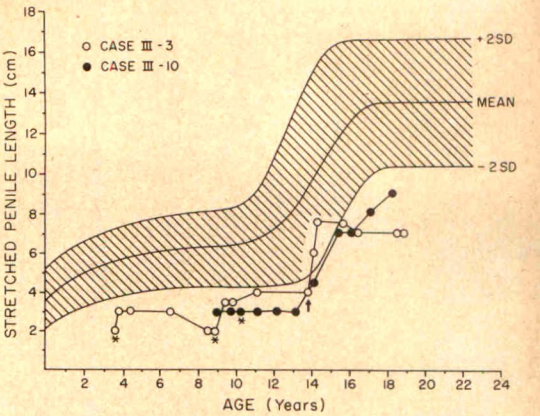

Fig 2.—Penile growth of subjects III-3 and III-10 compared with normal mean ± 2 SD (shaded area). Subject III-3 was treated twice with 0.2% testosterone cream (*) and with intramuscular testosterone enanthate injections (↑). Subject III-10 was treated for four months with testosterone cream (*). Normal stretched penile lengths were derived from Schonfeld.[24]

measured 2¼ × 1¼ cm bilaterally. There was a prominent scrotal raphe. Bone age was consistent with chronological and height ages. At that time, topical therapy with 0.2% testosterone cream was administered three times a day for four months. This resulted in penile enlargement to 3.0 cm stretched length and the appearance of a minimal amount of pubic hair. This response was less than that usually seen.

At 8½ years of age, penile length had regressed to about 2 cm (Fig 3), and topical treatment was reinstated for a 16-month period. Although the penis rapidly grew to 3.5 cm, no additional growth was observed at 9 years 10 months of age, and therapy was stopped.

Because of severe psychological problems related to penile size, therapy with 200 mg of intramuscular testosterone enanthate every four weeks was started at 13 years 10 months of age. Prior to this therapy, his penis measured 4 cm stretched length and 1.5 cm in diameter. His plasma testosterone level was 39 ng/dL (Table). After six months of treatment, his penis increased to 7.5 cm in length, and treatment was discontinued. Also, pubic and axillary hair appeared (Tanner stage 2). Subsequent examination showed no further penile growth (Fig 2).

At age 18 years 10 months, his right testis measured 3.6 by 2.2 cm, and his left measured 4.2 × 2.2 cm. Pubic hair of female distribution and axillary hair were at Tanner stage 4. Minimal bilateral gynecomastia was present. A semen sample, with a total volume of less than 0.25 mL, contained no sperm. His serum LH level was 121 ng/mL, 5 SD above the mean for a normal adult male (Table), and his serum FSH level was 403 ng/mL, 2.5 SD above the mean for a normal adult male. His plasma testosterone level was 738 ng/dL, which is in the normal range for adult males. Plasma progesterone level was 51 ng/dL (mean ± SD for normal adult males, 26 ± 4 ng/dL), and 17α-hydroxyprogesterone level was 341 ng/dL (mean ± SD for normal adult males, 94 ± 23 ng/dL). A pubic skin biopsy specimen was obtained to establish fibroblast monolayers to assess 5α-reductase and DHT-binding activity. The amount of 5α-reduced steroids after 30 minutes of incubation with testosterone was 648 pg/μg DNA, and after 60 minutes, it was 725 pg/μg DNA. These values were within the range for normal subjects.[6] A Scatchard plot, analyzed by linear regression of a DHT saturation curve, gave a maximum binding capacity of 306 moles × 10^{-18}/μg DNA and an apparent dissociation constant of 0.78 × 10^{-9}M. These values are in the normal range for our assay.[6]

Case 3.—The patient (III-10) was the maternal first cousin of patient 2 (III-3) and was a 3.970-kg infant. The pregnancy was complicated by polyhydraminos. The delivery was normal, but at birth the following physical anomalies were noted: a large head (head circumference, 37 cm, 98th percentile) with a frontal bossing, large tongue, and short blunted hands and feet. Body length was 57 cm, which is above the 98th percentile. The external genitalia were ambiguous. There was a small penis with chordee and perineoscrotal hypospadias. Only the right gonad could be felt in the bifid scrotum. The results of a buccal smear were negative for Barr chromatin bodies, and the karyotype was 46, XY. At 4 years of age, a retrograde cystourethrogram showed the presence of a rudimentary vaginal pouch that opened posteriorly and proximal to the external urethral sphincter. An exploratory laparotomy showed that both of the vasa deferentia were connected to the vaginal pouch and had to be resected when the pouch was removed. No left gonad could be found at that time. The histologic examination of a biopsy specimen from the right gonad showed an immature testis. The patient was subsequently admitted to a hospital on several occasions for repair of the hypospadias.

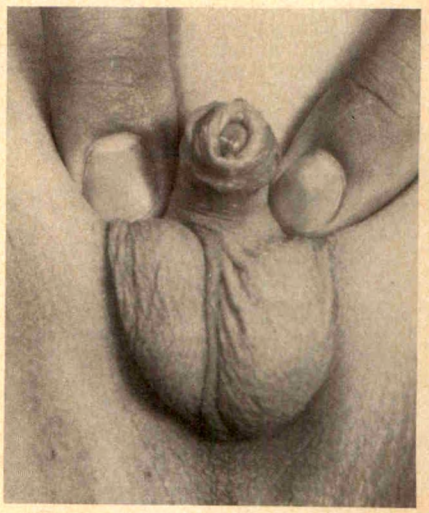

Fig 3.—Genitalia of subject III-3 at age 8½ years showing micropenis and prominent scrotal raphe. Testes are within scrotum.

He was first examined at The Johns Hopkins Hospital, Baltimore, at the age of

‡Concentrations were measured after treatment with human chorionic gonadotropin.

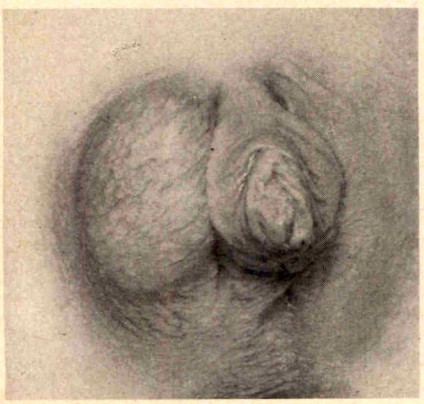

Fig 4.—Genitalia of subject III-10 at age 9 years showing small phallus, bifid scrotum, and absence of left testis.

9 years. His height was 149.2 cm (height age, 11 years, 7 months), and his weight was 52.2 kg. The same abnormalities of the face and extremities that were present at birth were noted. His penis measured 3 cm in length (Fig 2). The scrotum was bifid and contained only the right testis, which measured 1.25 × 0.75 cm (Fig 4). There was no sexual hair present. His serum LH level was 34 ng/mL, FSH level was 60 ng/mL, and plasma testosterone level was 10 ng/dL (Table). A five-month trial of topical 0.2% testosterone cream did not result in any appreciable growth of his penis (Fig 2).

Several investigations were performed in an attempt to rule out metabolic or endocrine disorders and cerebral gigantism. Renal function studies, including the results of urinalysis and an IVP, and serum creatinine and BUN levels, were normal. The protein-bound iodine, T_4 by column, and tests for urinary mucopolysaccharides showed normal results. There was a normal plasma growth hormone response to 0.5 g/kg of arginine hydrochloride in a 10% solution and to stimulation with 0.075 μ/kg of insulin (administered intravenously), and there was no paradoxical rise after glucose load. His scores on the Wechsler Intelligence Scale for Children showed a full IQ of 100.

Subsequent serum LH, FSH, and plasma testosterone determinations showed a progressive increase over the next six years (Table). A left testis, located in the inguinal canal, was first palpated at age 15½ years and was brought down surgically at 17 years, 4 months. At the time of orchiopexy, skin was obtained from the penis and the scrotum to establish fibroblast monolayers. 5α-Reductase activity was found to be normal: penile skin fibroblasts were normal at 993 pg/μg DNA at 30 minutes and at 1,260 pg/μg DNA at 60 minutes, and scrotal skin fibroblasts were normal at 559 pg/μg DNA at 30 minutes and at 976 pg/μg DNA at 60 minutes. The binding capacity and apparent dissociation constant of the DHT receptor from fibroblasts of the penis were 622 moles × 10^{-18}/μg DNA and 1.13 × 10^{-9}M, respectively. These values were within our normal range.[6] The scrotal fibroblasts also had normal DHT-receptors at 648 moles × 10^{-18}/μg DNA, with a high normal K_d at 2.78 × 10^{-9}M.

At age 18 years 4 months, his stretched penis measured 9 cm in length. His left testis measured 5.0 × 2.5 cm and the right measured 7.0 × 3.5 cm. Previous examinations over several years had also indicated a notable discrepancy in testicular size, with the right testis (which had been palpable throughout life) considerably larger, suggesting compensatory hypertrophy. The nipples were prominent, and the breasts were large and consisted mainly of adipose tissue. Pubic and axillary hair were at Tanner stage 5, with a normal male distribution. The beard was light and required shaving less than once a week. Plasma progesterone level was 21 ng/dL, which is in the normal range for adult males, while plasma 17α-hydroxyprogesterone level was 150 ng/dL, which is 2 SD above the normal mean.

COMMENT

The three patients described in the present report had various degrees of male pseudohermaphroditism. Patient III-3 had abnormally high levels of serum LH and FSH, while the plasma testosterone level was in the range for normal adult males. Patient III-10 had plasma androgen levels well above the normal range, with an abnormally high serum FSH level but a normal serum LH level. The finding of normal plasma testosterone levels combined with high LH or increased plasma testosterone levels and incomplete masculinization of the external genitalia suggests partial insensitivity to the action of androgens at the level of androgen-sensitive tissues, including the hypothalamus and pituitary. Plasma progesterone and 17α-hydroxyprogesterone levels were increased in patient III-3, but enzyme deficiency is unlikely because this patient had complete genital virilization but inadequate penile growth. For both of these patients, 5α-reductase activity in sexual skin fibroblasts was within the normal range, indicating that there was no defect in the conversion of testosterone to DHT in normally androgen-responsive tissues. Thus, these data suggest these patients have the incomplete form of androgen insensitivity, which was previously called Reifenstein's syndrome.[15] The patients had normal DHT-binding capacities, as did the previously reported cases,[6,7] and the cause of

their androgen insensitivity is unknown at present.

The phenotype of PAIS includes hypospadias with partial masculinization of external genitalia, gynecomastia, incomplete virilization at puberty, and sterility.[8,9] In this family with PAIS, affected members had variable phenotypic expression of androgen resistance, as previously noted by Wilson et al.[9] Their clinical phenotype varied from notable ambiguity of the genitalia (case 1, II-9) to almost complete masculinization (case 2, III-3). Minimal breast tissue could be palpated in both patients. During infancy and childhood, systemic and/or topical therapy with testosterone resulted in limited penile growth in patient III-3 and none in patient III-10. At puberty, despite adequate or excessive levels of endogenous plasma testosterone, penile length remained 2 SD below the normal mean for both subjects. The partial virilizing effects that occurred despite normal or high levels of plasma androgens are additional evidence for partial androgen resistance. Both patients are infertile: case III-3 had no sperm when semen was analyzed, and case III-10 had at least mechanical sterility since the distal portion of vasa deferentia was resected during removal of the vaginal pouch. Testicular biopsy to determine spermatogenesis was not done.

The combination of Wilms' tumor with or without nephron disorders and various types of male pseudohermaphroditism has been previously reported.[16-21] Because the kidneys and gonads arise from neighboring anlage, the ambiguous genitalia associated with Wilms' tumors are probably due to a primary injury of the gonadal anlage. In contrast, in our patient II-9, the family history suggests that the abnormal genitalia may have been due to a defect of the androgen receptors in target cells and that the Wilms' tumor was perhaps coincidental.

Total failure of virilization is seen in patients with CAIS. Two genetic variants have been described. One of them has deficient cytoplasmic androgen binding[3-5] that results from a mutation of the X-linked gene that specifies the DHT receptor,[22] as described in humans and the tfm/Y mouse.[23] The second variant has quantitatively normal specific cytoplasmic DHT binding in fibroblasts, and their defect is unknown, their pattern of transmission being compatible with either X-linked or sex-limited autosomal dominant inheritance,[4] the latter of which is less likely.

In PAIS, the level of DHT-receptor activity lies between normal levels and those of persons with CAIS[5,6] among some patients. Other patients have a similar phenotype, including partially masculinized external genitalia concomitant with increased plasma levels of androgens and gonadotropins but normal levels of DHT-receptor activity.[6,7] Both groups of patients respond poorly to androgen therapy. By analogy with the two variants of CAIS, patients with PAIS and normal DHT receptors are considered to have a partial form of the second variant of CAIS, like in the present family, which showed some response to testosterone therapy.

Management of Acute Asthma in Childhood

A Randomized Evaluation of β-Adrenergic Agents

Alan L. Schwartz, PhD, MD; Jeffrey M. Lipton, MD, PhD; David Warburton, MB; Lawrence B. Johnson, MD; Frank J. Twarog, MD, PhD

• **We examined the efficacy of several β-adrenergic agents commonly used to treat asthma and evaluated the optimum route of administration. Two hundred and sixty-nine persons aged 5 to 21 years who came to the emergency ward while suffering from acute asthma were treated with either (1) inhalation isoetharine hydrochloride or (2) subcutaneous epinephrine or terbutaline sulfate. Patients were evaluated using clinical scores and pulmonary function tests and were monitored for adverse side effects. Regardless of mode of therapy, the acute attack was either treated successfully, terminated in hospital admission, or required further therapy within 24 hours in a comparable number of patients. Adverse side effects were more common with terbutaline sulfate than with either epinephrine or isoetharine in the doses used. Thus, inhalation of β-adrenergic agents is as effective as subcutaneous administration in the treatment of acute asthma in childhood.**

(*Am J Dis Child* 134:474-478, 1980)

From the Department of Medicine (Drs Schwartz, Lipton, Warburton, and Johnson) and the Division of Allergy (Dr Twarog), Children's Hospital Medical Center, Boston, and the Department of Pediatrics (Drs Schwartz, Lipton, Warburton, Johnson, and Twarog), Harvard Medical School, Boston. Dr Warburton is now with the Department of Pediatrics, Children's Hospital of Los Angeles.

Acute asthmatic attacks constitute a major therapeutic problem in the physician's office and the emergency ward. Recommended guidelines for treatment have been published.[1-3] However, the availability of new β-2 selective adrenergic agents[4,5] necessitates a reevaluation of recommended regimens. The purpose of this study was twofold: first, to compare the efficacy of subcutaneous epinephrine with terbutaline sulfate; and second, to compare routes of administration of adrenergic agents (subcutaneous vs inhaled) in an acute care setting.

Subjective and objective criteria were used to assess the efficacy of each regimen and to monitor for adverse side effects. The results have demonstrated equivalent efficacy for all regimens studied. Thus, inhalation of β-adrenergic agents is as effective as subcutaneous administration.

MATERIALS AND METHODS

Treatment Protocols

Parenteral.—Epinephrine and terbutaline sulfate were prepared in double-blind coded vials by our pharmacy at a concentration of 1 mg/mL (Fig 1). These agents were administered at 15-minute intervals to a total of three doses (0.01 mg/kg, with a maximum dose of 0.4 mL). When required, further therapy was provided by inhaled isoetharine hydrochloride (Bronkosol). After two doses of isoetharine, aminophylline was administered intravenously (5 to 7 mg/kg during 20-minute period), if clinically indicated. Ten minutes after completion of the aminophylline administration, a decision regarding discharge or admission to hospital was made by the house officer and senior resident in charge of the emergency ward.

At any stage in this regimen, treatment was discontinued and the patient discharged from the emergency ward when he/she was clinically judged to be free of asthma by resolution of respiratory distress and improvement in auscultatory findings. Neither clinical scoring nor pulmonary function measurement was used in this clinical decision, as it was not known in advance what degree of improvement in these measurements would correlate with clinical resolution of asthma. Patients were given epinephrine (Susphrine) (0.005 mL/kg) and a dose of oral theophylline (5 mg/kg) before discharge if no intravenous (IV) aminophylline had been administered.

Inhalation.—Therapy was provided by inhalation of 0.5 mL of isoetharine hydrochloride in 2 mL of saline solution delivered by intermittent positive pressure breathing (IPPB) using a respirator powered with 40% oxygen at a pressure of approximately 15 cm H_2O. This was repeated when necessary for a total of three treatments at 20-minute intervals. Further therapy included up to two doses of a subcutaneous adrenergic agent (double-blind) and, if required, IV aminophylline. Discharge or admission was managed as outlined previously.

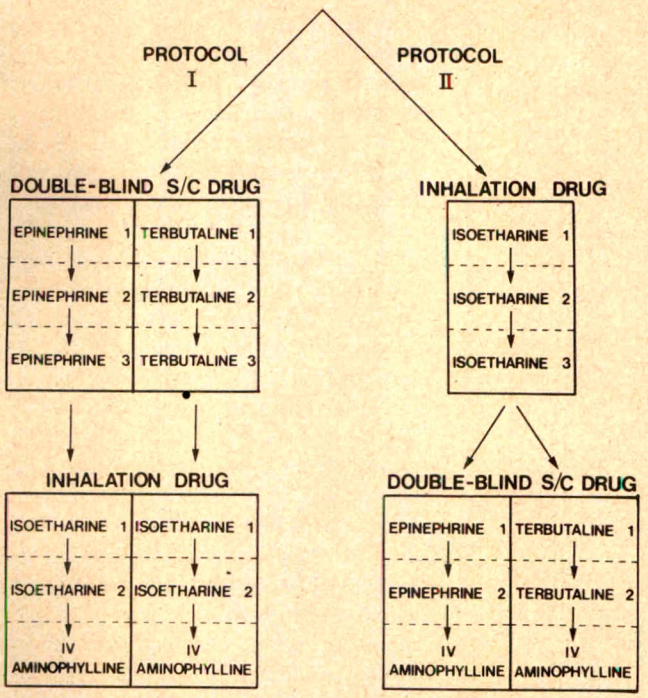

Fig 1.—Protocol for treatment of acute asthma. S/C indicates subcutaneous; IV, intravenous.

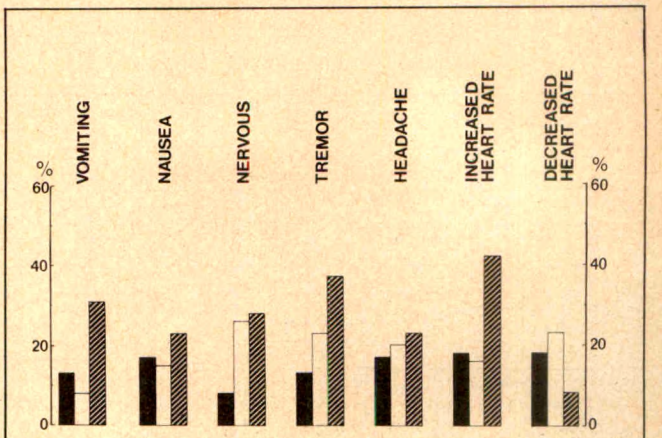

Fig 2.—Frequency of adverse side effects in patients receiving isoetharine hydrochloride, epinephrine, or terbutaline sulfate. Side effects were evaluated only for the first administered drug in each protocol. Change of 20 beats per minute or more above or below pulse rate measured at time of admission was considered significantly increased or decreased rate, respectively. Total number of patients receiving each medication; isoetharine, 127 (solid bar); epinephrine, 61 (open bar); terbutaline, 66 (hatched bar).

Selection of Patients

Patients with a diagnosis of acute asthma who were between the ages of 5 and 21 years and who came to the emergency ward were eligible. They were excluded if they had received parenteral therapy for the present attack, were in "impending respiratory failure," were pregnant, or were experiencing their first attack of asthma. Informed consent was obtained and assignment made on a random basis to one of the three protocols (Fig 1).

During the four-month study period, 509 visits were made to the emergency ward for acute asthma by persons eligible for the study: (1) 10% (50/509) were judged to be "too ill" to participate, and 50% (25/50) of these were admitted to the hospital; (2) 35% (179/509) declined to participate in the study, and 13% (23/179) of this group were admitted to hospital; (3) 55% (280/509) enrolled in the study, of whom 6% (18/280) were admitted to hospital. Four patients (4/280) who volunteered for the study were withdrawn immediately after receiving their first medication and were admitted to the hospital. In addition, seven patients (7/280) were not evaluated due to lost vial codes.

The 269 visits included in this study comprised 188 individual patients: 82% of these were studied once; 9%, twice; 5%, three times; and 4%, four or more times. Complete data were obtained on 254 of

these 269 visits. Eighty percent of all the patients were contacted by telephone within 24 to 36 hours to determine whether further therapy was required or had been obtained through other sources.

The factors precipitating an acute asthmatic episode are frequently multiple and are difficult to determine. Of the participants in this study, 22% (57/254) reported upper respiratory tract symptoms with or without fever preceding the onset of asthma. One patient had pneumonia.

One hundred and forty-two subjects (53%) were assigned to the parenteral protocol and 127 (47%) to the inhalation protocol. Epinephrine was given to 66 (47%) and terbutaline to 76 (54%) in the parenteral protocol.

Clinical Evaluation

The clinical scoring systems of Wood et al[6] and Pierson et al[7] were modified by the addition of one point for heart rate greater than 108 beats per minute and one point for respirations greater than 28/min (Table 1). This modification was devised after analysis of vital signs and measurement of forced expiratory volume in one s (FEV_1) for the first 30 subjects studied showed that heart rate greater than 108 beats per minute and respiratory rate greater than 28/min correlated with a significant decrease in FEV_1 ($P < .05$).

Clinical scores were obtained prior to each administration of medication and at the time of discharge or admission to hospital. Complaints of nausea, headache, or nervousness were recorded and observations were made for vomiting, tremor, or tachycardia during these examinations to monitor for adverse side effects. This clinical evaluation was performed by the house staff assigned to the emergency ward at the time of this study.

Pulmonary Function Testing

Pulmonary functions were measured using an electronic spirometer. Although parameters recorded included forced vital capacity, FEV_1, forced expiratory flow 25% to 75% (expressed as percent predicted for age and height), and peak expiratory flow (expressed as liters per s), only FEV_1 is presented as being representative of pulmonary status. The best result of two separate trials was recorded initially. Subsequent results were based on a single recording. Statistical comparisons were performed using Student's t test.

RESULTS

The acute asthmatic attack was successfully treated in 71% (196/276) of all subjects during the first phase of therapy. The percent of patients clinically improved and discharged from the emergency ward was similar for each treatment regimen (Table 2). These groups were comparable ($P > .05$) on the basis of both clinical scores and FEV_1 (Table 3). The conditions of approximately 25% of all the patients improved sufficiently to be discharged at each successive dose of medication administered during the first phase regardless of either the pharmacologic agent used or the route of administration.

The conditions of approximately another 20% improved with further adrenergic therapy in the second crossover phase. Only 26% (5/19) of all those who required IV aminophylline after administration of the adrenergic agents were subsequently discharged home. Treatment failures resulting in admission to the hospital occurred after each protocol.

Nine percent (24/255) of all those discharged returned for further acute care within 24 hours. Telephone follow-up of 80% of all the patients indicated that none were treated at other facilities. Returns were equally distributed among the different regimens and were nearly as common in subjects discharged after a single adrenergic agent (epinephrine, 4/51; terbutaline, 3/52; isoetharine, 8/93) as in those receiving both subcutaneous and inhalation drugs (epinephrine and isoetharine, 2/13; terbutaline and isoetharine, 2/17; isoetharine and epinephrine, 4/18; isoetharine and terbutaline, 1/11) during the first visit.

Of the 254 subjects, 169 (76%) from whom the information was available reported taking theophylline within 24 hours, and half of all these (83/169) within three hours prior to entry into the study (Table 4). These patients were equally distributed among all the treatment groups. Of those reportedly taking theophylline within three hours of emergency therapy, 78% were discharged after receiving only one drug, the same rate as that for the entire study population (209/269, 78%). The results of emergency treatment were comparable for persons receiving other outpatient medication regimens, except for those receiving corticosteroid preparations, of whom 93% responded to the first phase of therapy.

Clinical Score and Pulmonary Function Assessment

There was no statistical difference between the groups of patients when clinical scores and FEV_1 were compared ($P > .05$) (Table 3). The mean clinical score on entry into the study was greater than 6, and FEV_1 less than 30% of that predicted. There was a comparable and significant decrease in clinical score and increase in FEV_1 ($P < .005$) after the first phase of all three therapeutic regimens.

Adverse Side Effects

Adverse side effects were tabulated only for the first phase of therapy. Tremors, vomiting, and increases in

pulse rate occurred most frequently with terbutaline (Fig 2). Theophylline preparations taken within three hours of therapy did not increase the incidence of complications associated with the adrenergic therapy.

COMMENT

This clinical trial has demonstrated that epinephrine, terbutaline and isoetharine, all β-adrenergic agents, were equally effective in the treatment of acute asthma in children. Both the subcutaneous and the inhalation routes of administration proved to be equally effective. The conditions of similar numbers of patients in each therapeutic regimen were successfully treated or required further treatment and admission of the patient to the hospital. Furthermore, the conditions of a comparable percent of patients improved clinically, and the patients were discharged home at each sequential dose of medication administered in each of the regimens. Repeated administration of adrenergic agents in this age group is warranted as the conditions of a large number of patients improved sufficiently to allow discharge, even after the fourth dose. Return visits for further therapy within 24 hours occurred equally in all treatment groups. More rigorous control of postdischarge therapy with a bronchodilator may have reduced this rate of returns.

Frequency of adverse side effects was highest in those patients treated with terbutaline. Complications most frequently noted were tremor, vomiting, and tachycardia. The adverse effects observed were generally minor and did not require discontinuation of therapy. Others who compared the efficacy of terbutaline with epinephrine for the treatment of asthma[8-13] have also reported more frequent side effects with terbutaline.[8-10,12,14] These adverse reactions are dose-dependent in adults, with decreased frequency when the dose is reduced from 0.5 to 0.25 mg.[10,13,14] A similar decrease in reactions also might be expected in children with a reduction in dose or frequency of administration; however, our data do not allow us to determine whether the efficacy would be equivalent.

Although attacks could be treated effectively by either the parenteral or the inhaled routes, several factors should be considered when using inhaled adrenergic agents. An increase in hypoxemia that may be the result of aggravated ventilation perfusion mismatch occurs with inhaled adrenergic drugs.[15,16] This complication also occurs with aminophylline and epinephrine,[17,18] but may be avoided in either case by increasing the fraction of inspired oxygen.[15] Tachyphylaxis and even paradoxical bronchoconstriction have been reported to occur in patients who have abused inhaled adrenergic drugs.[19-21] Occasionally, bronchoconstriction occurs without previous abuse.[20,22,23] These factors should be recognized as a possible cause for inadequate response or deterioration in the course of therapy with inhaled adrenergic agents.

Equivalent bronchodilation has been demonstrated with adrenergic agents administered either by positive pressure or by nebulization.[24-27] Intermittent positive pressure breathing was used in this trial as it was the customary mode of aerosol delivery in our hospital at the time. At the present time, inhaled adrenergic aerosol agents are administered by nebulization. Although no complication occurred with the use of IPPB, pneumothorax may result from this mode of therapy and has been implicated in asthma deaths.[28]

Based on the results of this study, the following recommendations are made for the management of acute asthma in childhood: (1) There was no therapeutic difference among the adrenergic agents studied and, therefore, epinephrine, terbutaline, or isoetharine can be used with equal efficacy. However, to decrease the incidence of adverse side effects with terbutaline, the dose should be reduced or the interval between doses increased. (2) Repeated administration of adrenergic agents in this age group is warranted as a large proportion of patients responded even after the fourth dose. (3) Since adrenergic agents can be administered with equal efficacy either subcutaneously or by inhalation, the latter route of delivery should be considered as a reasonable alternative to the traditional subcutaneous epinephrine in the management of acute asthma in childhood. (4) In a patient unresponsive to repeated administration of an adrenergic agent, admission to hospital should be anticipated as administration of IV aminophylline is unlikely to result in sufficient reduction in symptoms to allow discharge. (5) As terbutaline is not presently recommended for use in children younger than 12 years of age, a decision with regard to potential benefits must be made for each individual case.[29] (6) Significant residual pulmonary function abnormalities persist in children who are clinically recovered from an acute episode of asthma, and therefore continued therapy with a bronchodilator after treatment is essential.

This study was supported in part by Public Health Service grant AI 11419, and by Medical Foundation grant 1553 to Dr Twarog.

P. Gazarra, of the Life Support Equipment Corp, provided the electronic spirometer (Vanguard Model DS 500) used in this study.

The medical house staff, the emergency ward nurses and personnel, and the pharmacy of Children's Hospital Medical Center, Boston, and K. Lahey, RN, assisted in this study; R. S. Geha, MD, and D. J. Strieder, MD, gave critical evaluation of the manuscript; M. E. Avery, MD, I. Franz, MD, and A. Broseghini, MD, gave support; and Cathy Clark gave secretarial assistance.

60 YEARS AGO IN THE AJDC

Water Retention in Pneumonia

Over a period of five years the authors observed cases of lobar pneumonia among children under 2 years of age in which the sudden defervescence of fever (by crisis) was accompanied by a loss of weight. This frequently occurred within 24 hours of the subsidence of fever and averaged 9.6 ounces among this group of twenty-eight children. There were twenty-two cases of lobar pneumonia in which the fever did not subside promptly or in which complications occurred. Among this group five had no weight loss, and the remainder lost weight gradually over a period of days.

The authors observe that this rapid resolution is associated with an increase in urine volume output as well as urinary chlorides and nitrogen. 1916 studies with a skin elastometer had demonstrated the presence of edema in both children and adults during bouts of pneumonia. The authors suggest water retention may be related to heat retention and that "with restoration of the water-binding power of the tissues to the normal . . . , water would be liberated for heat regulatory purposes. . . ." Diphtheria-Tetanus Skin Testing

Its Clinical Value for Delayed Hypersensitivity

Donald B. Kaufman, MD; Wanderley C. deMendonça, MD; Joel Newton, MD

• Skin testing as an in vivo means of evaluating cell-mediated immune function is extremely valuable. However, problems lie in selecting the appropriate antigens and interpreting the results. The suggestion that diphtheria-tetanus would provide a good antigen in infants and children was evaluated by comparing skin test observations with results of skin biopsy examinations. Thirteen subjects, seven of whom were immunodeficient, were evaluated by skin reactions and dermal biopsy specimens. Fifty percent of the immunodeficient patients had positive skin test reactions but had biopsy specimens that were not consistent with delayed-type hypersensitivity (DTH). Although all normal controls on whom biopsies were done had histologic DTH reactions, two had negative or equivocal skin reactions. Our data suggest, on the contrary, that delayed hypersensitivity testing with this antigen is not a good screening test for disorders of immunity or inflammation.

(*Am J Dis Child* 134:479-483, 1980)

Testing for cell-mediated immunity is one of the more important aspects of diagnosing immunodeficiency disorders. The most currently available techniques require sophisticated in vitro testing. However, the cutaneous delayed hypersensitivity reaction is a safe, reliable, and easily available test for in vivo screening. When properly performed, it can give useful information on cell-mediated immunity in general and on the inflammatory response.[1,2]

There are several limitations to this test. Prior exposure to the antigen tested must have occurred, a situation not always easy to assess and often not present in the very young. In young children where there is a general lack of exposure to the commonly used test antigens, such as streptokinase-streptodornase, monilia, and trichophyton, positive reactions in children younger than 6 years old for streptokinase-streptodornase, younger than 7 months old for monilia, and younger than 16 years old for trichophyton are not usually expected. In addition, children's skin often react differently from adult skin and the criteria for positive reactions may vary. Furthermore, the reaction must be read at various times since there are often three stages that can be recognized (immediate, Arthus-type, and delayed) and improper interpretation may lead to false-positive or false-negative results. The immediate reaction, which is a wheal and flare, occurs at around 20 minutes postinjection and may persist for up to two hours. It is an allergic-type reaction resulting from the activation of IgE antibodies and the release of vasoactive amines, such as histamine. The Arthus reaction occurs from two to eight hours after injection and is an antigen-antibody or immune complex reaction involving IgG and complement. It is primarily an acute inflammatory reaction. Often, this reaction may persist for 24 hours or longer making the reading of a delayed-type hypersensitivity (DTH) response at 48 hours difficult to interpret. The DTH response is a cellular immune response involving primarily lymphocyte sensitization and occurs between 48 and 72 hours.

Facktor et al[3] have previously pointed out some of the difficulties associated with skin test interpretation in their study using tetanus toxoid (TT). Approximately 63% of their patients demonstrated an immediate reaction and 32% an Arthus reaction, whereas only 74% showed a delayed hypersensitivity reaction.

Recently, Franz et al[4] reported on the use of diphtheria-TT as a skin test antigen for DTH in a pediatric population and suggested that this may be a useful test for assessing cell-mediated immunity (CMI). They studied 114 subjects of various ages. By their criteria, 100% of infants 7 to 12 months old had positive skin tests and 88%, including those without immunization, between 1 and 5 years of age. Since most infants are immunized with diphtheria-tetanus (DT) beginning at 1 to 2 months of age and a

history is easily obtainable, a skin test for DTH could provide valuable information in evaluating potentially immunologically incompetent children.

Unfortunately, their report only assessed the presence or absence of skin reactivity and no objective evidence was presented to substantiate whether these were delayed hypersensitivity reactions or not. In addition, only two patients with immunodeficiency were studied, one having an antibody-deficiency syndrome. We, therefore, evaluated the DT skin test response by visual measurements and histologically by punch biopsy on a series of patients seen in our immunology clinic.

MATERIALS AND METHODS

Informed consent was obtained from patients undergoing intradermal skin testing and punch biopsy. All patients were tested for cell-mediated and humoral-mediated deficiency, as well as disorders of inflammatory responses by standard in vitro techniques. These tests included quantitative immunoglobulins, antibody titers, and a variety of antigens, including diphtheria, rubella and streptolysin O, E rosettes, phytohemagglutinin (PHA) response, complement, quantitative nitro blue tetrazolium assay, and chemotaxis. Only those patients with a documented history of diphtheria-pertussis-tetanus immunizations or a recall booster within one year of this study were included in this evaluation. Biopsy specimens were taken from two normal volunteers with positive

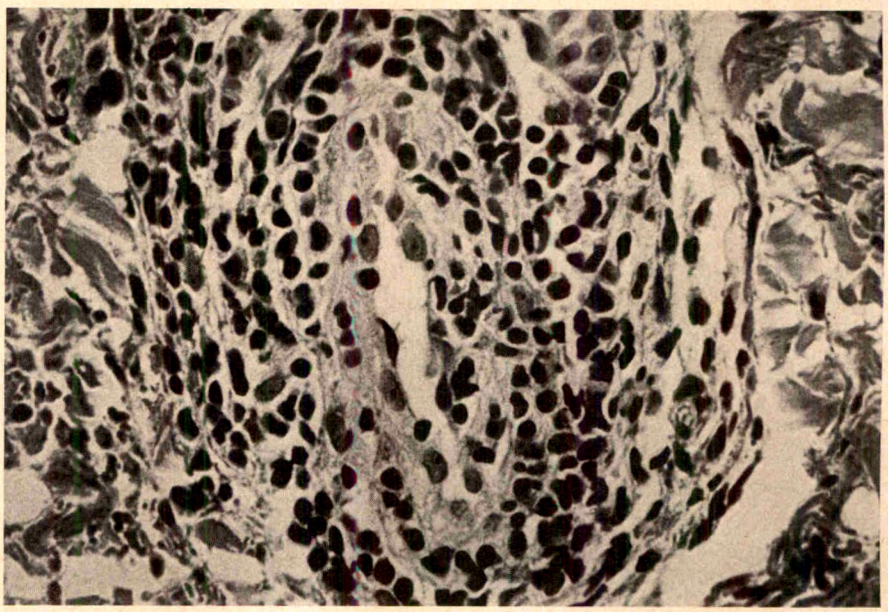

Fig 1.—Represents typical type IV delayed-type hypersensitivity cell-mediated immune response with perivascular lymphocytic infiltrate.

PPD (intermediate strength) skin tests for comparative purposes (Bacillus-Calumet-Guerin immunized). The normal controls were all healthy individuals known to the principal investigators and ranging in age from 4 to 38 years, whereas the patient population consisted of those individuals seen in the immunology clinic with suspected or proved immunodeficiency. They ranged in age from 17 months to 24 years (Table 1).

Diphtheria-TT, absorbed (pediatric DT) diluted 1:100 was used. In some cases, a dilution of 1:50 and 1:10 was used. An intradermal inoculation of 0.1 mL was injected and a wheal raised. Reactions were read at 30 minutes, and at 4 to 12, 24, 48, and 72 hours. Reactions were measured for the greatest diameter of erythema and induration with use of a clean, circular plastic millimeter ruler. All patients were matched for interval from vaccination to skin testing, and skin tested with the same lot of DT toxoid.

A 3-mm punch biopsy specimen was obtained under local anesthesia at the site of injection at 72 hours if any reaction at all had been seen during the previous observation period. Biopsy specimens were fixed in a 10% formaldehyde solution, stained with hematoxylin-eosin, and read by two independent observers (J.N. and W.M.) without any prior knowledge of the history or laboratory findings. The histologic criteria for a delayed hypersensitivity and for an Arthus-like reaction have been well described.[5,6] Briefly, a delayed hypersensitivity reaction is characterized by a dense mononuclear cell infiltrate (macrophages and lymphocytes) with occasional neutrophils and basophils, whereas the Arthus reaction is characterized by an acute inflammatory-type reaction with leukocyte clumping, platelet aggregates, and a noticeable neutrophilic accumulation (Fig 1 to 3).

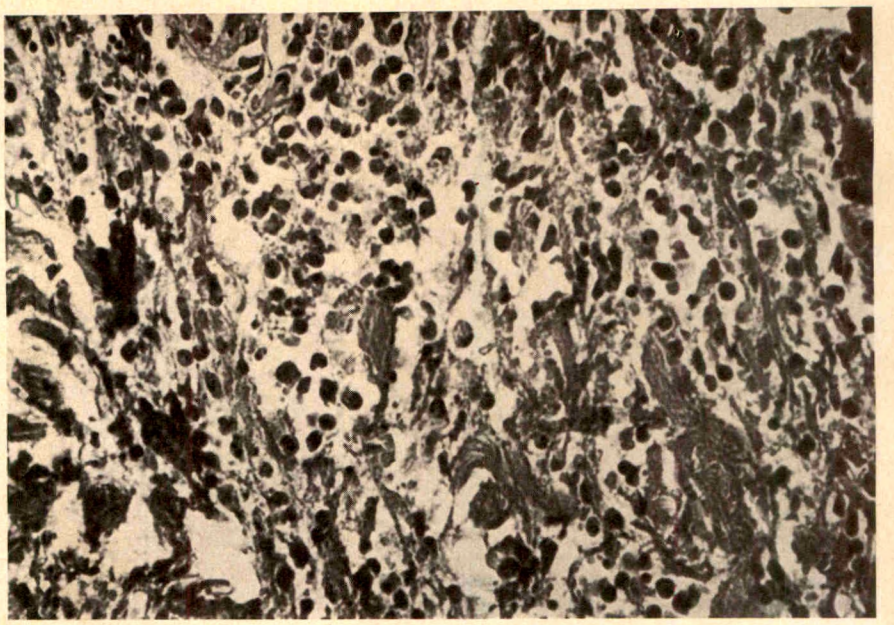

Fig 2.—Arthus-like reaction with acute necrotizing vesicular dermatitis associated with noticeable neutrophilic inflammatory response. Rare eosinophils and mononuclear cells are present.

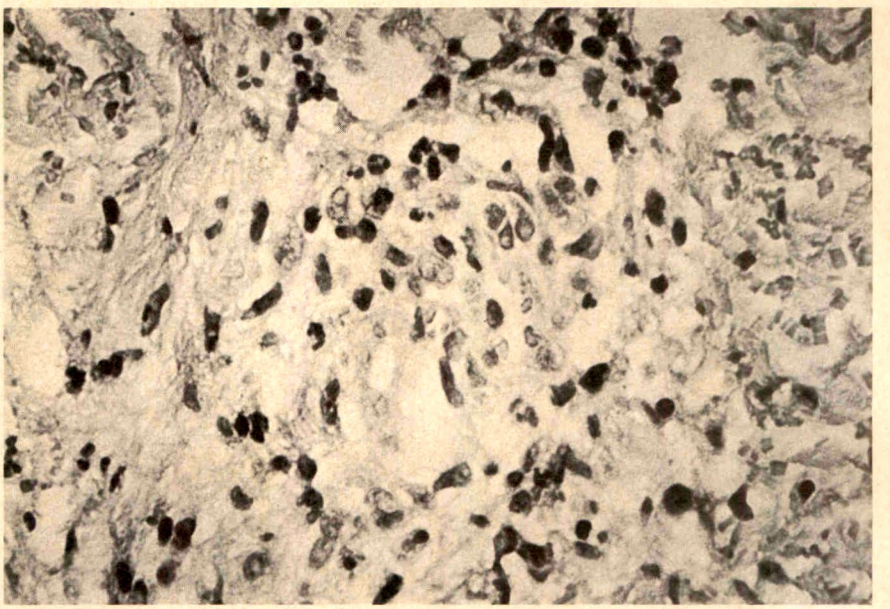

Fig 3.—Nonspecific inflammatory response with some features of both an Arthus and delayed-type hypersensitivity response. Infiltrate is predominantly neutrophilic with some perivascular response consisting of occasional lymphocytes, monocytes, and eosinophils.

RESULTS

The conditions of 13 subjects were completely evaluated. Of these, seven had some type of immune defect, including three with combined immunodeficiency. Reactions of 2 mm or less were difficult to measure accurately. Two patients did not undergo biopsy because no reaction was observed. The data from the visual observations are given in Table 1, whereas the histological data are given in Table 2.

If one uses the criterion of Pepys[7] (induration $\geq$ 10 mm at 48 hours) 2/6 or 33% of the normal controls were positive at 48 hours and one at 72 hours, whereas 2/7 or 29% of the patient group were positive at both 48 and 72 hours. If, however, one uses the criterion proposed by Franz et al[4] ($\geq$ 2 mm), 5/6 of controls were positive at 48 hours and 72 hours and 5/7 of the patients were positive at the same time. One normal control (skin test positive for monilia) and two patients (combined immunodeficiency [SCID]) had no reaction at all, with 1:100 dilution. For purposes of this article, positive skin tests to antigens other than DT were defined as induration greater than 5 mm at 48 hours and for DT greater than 2 mm.

Of the patients on whom biopsy was done, 3/6 (50%) demonstrated an Arthus-like reaction rather than de-

layed hypersensitivity despite the fact that these three all had positive-appearing skin tests by observation and 2/3 were known to have combined immunodeficiency. Of the two other patients who underwent biopsy, the histologic reactions correlated poorly with the skin test readings despite the fact that both were considered positive (patients 12 and 13). Only one patient with SCID showed no reaction to the DT antigen. It is also interesting to note that three of the abnormal patient population had positive skin test reactions to streptokinase-streptodornase and/or monilia despite a questionable result in one and a negative result in the other two with the DT antigen (patients 13 and 14).

A dilution of 1:50 was used in four individuals, three controls and one abnormal (patient 15, Table 1) and were not different from the 1:100, other than a slight increase in erythema. Five subjects were tested with a dilution of 1:10. Two were nonimmune individuals who reacted with both erythema and induration immediately. Two were normal controls (patient 8, Table 1) who also showed positive results, and patient 15 who demonstrated a defective in vitro CMI had a nonspecific reaction at 1:10.

COMMENT

The value of delayed hypersensitivity testing for evaluation of cellular immune competence is generally considered to be established. The major clinical problem lies in the appropriate selection of antigens in the young child or infant. Monilia *(Candida albicans)* antigen, which has the greatest exposure rate, is an excellent antigen but still occurs in only 60% to 80% of the infants older than 7 months of age, and even all of these patients do not demonstrate positive skin test reactions.[8,9] The use of dinitrochlorobenzene poses problems in terms of required sensitization and the subsequent adverse responses, such as sloughing and scarring. The use of PHA as a skin test has proved useful to some investigators, but the correlation with in vitro studies has not been good and caution in the interpretation of both positive and negative results is necessary.[10]

The use of a specific antigen for skin testing would be extremely advantageous. With the routine use of DPT and measles, mumps, rubella vaccinations in children, an appropriate skin test antigen from one of these would be extremely valuable. Unfortunately, the use of mumps as an antigen has been of limited value because of the high degree of primary irritation and perhaps reactions to contaminating antigens.[11,12] Similarly, TT, which is advocated by some also shows a high degree of immediate and Arthus-type reactions and is, therefore, difficult to interpret.[3] Whether this phenomenon also relates to the reactions herein noted with DT is unknown at the present time. It would seem that TT does cause more reactions. Part of the problem may lie in the hyperimmunization that occurs with TT which, at least in the younger children, does not seem to be the case in our study. The question is raised if it would be better to develop an antigen for diphtheria skin testing that lacks tetanus. In this regard, Kuhns and Pappenheimer[13] reported a high incidence of immediate wheal and flare reactions to diphtheria toxoid in allergic as compared with nonallergic individuals.

Facktor et al[3] studied 70 normal individuals with TT, mostly in the older age group, and as noted previously, they demonstrated a high incidence of "reactions." However, biopsy specimens were taken in a few selected individuals to look for specific reactions. It is, therefore, difficult to compare their results either with those of Franz et al[4] or ourselves. Steele et al[9] demonstrated that tetanus was a better single screening antigen than monilia, the most often used single antigen. Similar studies with diphtheria alone have not been done. Thus, the issue has not been resolved, but at least theoretically diphtheria alone might be a better skin test antigen.

In this brief report, we have demonstrated that a high degree of irritant, immediate, and Arthus-type reactions do occur. Furthermore, there is a very

poor correlation between the histological results and the observed skin reactivity. A positive result at 48 or 72 hours, regardless of the criterion used for determining positivity, cannot safely be interpreted as reflecting CMI function. Some workers in the field have suggested the use of fluid TT often in the undiluted form. However, two points are worth mentioning. One is that fluid DT is no longer commercially available and, therefore, its value as a routine DTH test is restricted and it is often used at a concentration at least ten times greater than the 1:100 dilution in our study. In the study by Franz et al,[4] higher concentrations resulted in nonspecific reactions, particularly notable in that they occurred in unimmunized individuals.

We concur with their findings using less diluted antigen. Several patients tested with a 1:10 dilution comparable to the fluid DT had severe reactions, creating considerable discomfort to the patient. This also occurred in nonimmune individuals. Although the use of a 1:10 dilution may lead to more positive reactions it also increased the likelihood of adverse reactions and false-positive results.

We have no explanation as to why an Arthus-type reaction occurred only in suspected or proved immunodeficient patients. The lack of such reactions in the controls may be related to the numbers of patients evaluated or perhaps to a subtle defect in the complement activation pathway for C3 as has been proposed by Barandun et al[14] for reactions to immunoglobulins in immunodeficient patients.

We believe that if the DT toxoid delayed hypersensitivity skin test is to be used, it must be done in conjunction with a skin biopsy that, therefore, severely limits its usefulness as a screening test for disorders of immunity or inflammatory response. Thus, as a routine assay it is not recommended. It should also be noted that the standard criteria of 10 mm of induration used for assessing PPD reactions and other skin tests in adults is not applicable in children.

Our data would support the view shown by others, that since there does not seem to be any single antigen that is suitable for skin testing, multiple skin test antigens should be used for assessing delayed hypersensitivity responses. Our data would also support the view that the results of such testing be interpreted with caution and that, depending on the degree of clinical suspicion in any individual, more sophisticated tests, eg, lymphocyte stimulation, may be warranted to evaluate CMI.

The Michigan State Department of Public Health supplied the diphtheria-pertussis-tetanus material and did the measurement of diphtheria antibodies.

Editorial Life in the 14th Century

Multiple copying of manuscripts was no longer the monopoly of lonely monks in their cells but the occupation of professional scribes who had their own guilds. Licensed in Paris by the University, supposedly to ensure accurate texts, the scribes were the agony of living authors, who complained bitterly of the copyists' delays and errors. The "trouble and discouragement" a writer suffers, wailed Petrarch, was indescribable. Such was the "ignorance, laziness, and arrogance of these fellows" that when a writer has given them his work, he never knows what changes he will find in it when he gets it back.

Circumcision and the Risk of Cancer of the Penis

A Life-Table Analysis

Mosze Kochen, MD, MPH, Stephen McCurdy, MPH

• The low incidence of penile cancer in the United States is frequently cited as a reason for not justifying the risk of neonatal circumcision as a prophylactic measure. Although uncircumcised men are uniquely at risk for this malignant neoplasm, previous approaches have used annual incidence data collected without regard to circumcision status, thus tending to underestimate the true risk to this susceptible group. In addition, the concept of lifetime risk has not been addressed. Using data from the Third National Cancer Survey and previously published circumcision prevalence figures in a life-table analysis, we estimated the lifetime risk for cancer of the penis in uncircumcised males. The predicted risk is 166 per 10^5, or one in 600; the estimated median age of occurrence is 67 years. These data deserve to be considered with other morbidity factors in the context of the neonatal circumcision debate.

(*Am J Dis Child* 134:484-486, 1980)

Circumcision, one of the most common surgical procedures on male subjects in the United States, continues to be controversial in terms of risks and benefits involved. Among the many points of debate is the protective value of the operation against cancer of the penis vs the morbidity of the procedure. The American Academy of Pediatrics states that circumcision is an effective method of preventing cancer of the penis.[1] It has been maintained, however, that in spite of this protective effect, the incidence of cancer of the penis is so low as not to justify the risks of circumcision.[2]

Incidence data for this malignancy are based on the number of cancers per year in 100,000 men, without regard to circumcision status. Since uncircumcised males are essentially the only population at risk, these figures underestimate the incidence of cancer of the penis in this uniquely susceptible group. In addition, annual incidence data do not address the lifetime risk for this cancer.

To contribute to the evaluation of neonatal circumcision from the standpoint of penile cancer prevention, we present an analysis of the lifetime risk of cancer of the penis in uncircumcised males.

SUBJECTS AND METHODS

Age-specific incidence rates for cancer of the penis in US males were obtained for the years 1969 to 1971 from the Third National Cancer Survey.[3] We assumed that virtually all of the reported cancers occurred in uncircumcised males. We therefore adjusted the rates for the estimated fraction of the population that was uncircumcised in each age group. Here we relied on circumcision prevalence values published in 1968 by Stern and Lachenbruch.[4] Their figures are based on physical examination of a nonrandom sample of 330 men. The fraction of uncircumcised men in each age group is given in Table 1, column 3.

Our adjusted age-specific rates were then applied to the US life table of 1971[5] for males of all races. This yielded the cumulative lifetime risk of cancer of the penis in uncircumcised males.

RESULTS

Table 1 summarizes the rate adjustment procedure and shows age-specific risk rates for cancer of the penis in uncircumcised men. These adjusted rates are applied to the 1971 US life

Table 1.—Adjustment of Age-Specific Incidence Rates for Cancer of the Penis

Age Group x_i-x_{i+n}, yr	Crude Incidence for Penile Cancer, 10^{-5} per Year*	Uncircumcised Fraction of Age Group[4]	Adjusted Risk Rate for Uncircumcised Men, 10^{-5} per Year
0-30	0.0	. . .	0.00
30-35	0.1	.39	0.26
35-40	0.4	.39	1.03
40-45	0.5	.50	1.00
45-50	0.9	.50	1.80
50-55	1.3	.54	2.41
55-60	2.6	.54	4.81
60-65	3.4	.56	6.07
65-70	5.4	.56	9.64
70-75	5.8	.45	12.89
75-80	4.9	.45	10.89
80-85	8.3	.45	18.44
85+	7.8	.45	17.33

table as given in Table 2. This yields a value of 166 per 10^5, or one in 600, as the cumulative lifetime risk for this malignant neoplasm; the predicted median age of occurrence is 67 years.

COMMENT

Penile Cancer

Cancer of the penis is rare in the United States (annual age-adjusted incidence 1.0 per 10^5 for 1969 to 1971).[3] The lifetime risk of having this condition was indirectly estimated. This analysis emphasizes incidence and does not specifically predict morbidity or mortality for those contracting the disease. At present, the major morbidity can be ascribed to the psychological and physical trauma of the disease and its therapy (usually surgery).

The median survival time for 67-year-old men (the predicted median age for getting penile cancer) is 7.5 years.[6] Life expectancy for unaffected men at this age is 12.1 years.[7] From this, one may roughly estimate 4.6 years of life lost per cancer, or more than 750 years per 10^5 uncircumcised men. To cause a comparable loss of years of life, circumcision would have to be responsible for approximately ten deaths per 10^5 neonates, assuming a life expectancy of 76 years at birth.

However, morbidity and mortality issues become at least as much philosophical as medical concerns. They are also subject to change owing to advancements in therapy and its availability to the patient. Therefore, we choose to focus chiefly on the incidence of the disease.

Comparison with the lifetime risks of other malignant neoplasms aids in providing perspective and allowing interpretation of our figures. A similar analysis using the same data sources yielded 225 per 10^5 as the lifetime risk for cancer of the testes, more than 1,500 per 10^5 for cervical cancer, and 4,800 per 10^5 for cancer of the prostate. Thus, for every lifetime incident of cancer of the penis, there are 1.4 cancers of the testes, nine of the cervix, and 29 of the prostate.

Two Basic Assumptions.—The accuracy of our estimate for lifetime penile cancer risk depends on the validity of two major assumptions. The first is that these cancers occur exclusively in uncircumcised males. This allows one to adjust population-based incidence rates for the fraction of the population that is uncircumcised and, therefore, the fraction at risk. The peculiar susceptibility of uncircumcised males to this malignant neoplasm is well known.[1] Leiter and Lefkovits,[8] in a review of the literature since 1936, found only nine reports of cancer of the penis in neonatally circumcised males.

The actual values of the adjusted age-specific risk rates depend partly on the estimates for frequency of circumcision taken from Stern and Lachenbruch.[4] We are aware of no other age-specific circumcision prevalence data for the United States that are based on physical examination. Although other sources of estimates are available, these data are unreliable[9] in that they are based solely on inquiry.

Stern and Lachenbruch's figures are based on a nonrandom sample of men and may not adequately represent the diverse socioeconomic makeup of the US population. Error owing to this sampling bias would probably not have a great effect on the final value for estimated lifetime risk. To illustrate, let us assume the figures from Leiter and Lefkovits[8] systematically overestimate circumcision rates by 50% across all ages. Compensating for this assumed bias reduces the lifetime risk for cancer of the penis by 25%, to 124 per 10^5. The incidence rates taken from the Third National Cancer Survey[3] are also subject to error. The most likely direction of bias is underestimation of the true incidence owing to incomplete reporting. These neoplasms in older men may not come to attention, especially if death intervenes from an unrelated cause not requiring autopsy.

The second major assumption on which this analysis is based concerns the validity of applying to the birth cohort of 1971 the age-specific risk rates derived from the experience of much older cohorts. To address this assumption, one must consider the secular trend of penile cancer incidence. The incidence of this malignant neoplasm has remained at a low level and exhibits a decline during the last three decades. In 1947, the age-adjusted risk of penile cancer was 1.4 per 10^5 per year [10]; in the period from 1969 to 1971, it was 0.9 per 10^5 per year.[3] Part of this decline may be explained by improved economic and living conditions. To the extent that this is the case, our analysis will overestimate the lifetime risk for those born in 1971.

The decline may be due in part to a cohort effect, however; ie, increased circumcision rates in younger cohorts would contribute to the overall lower-

Table 2.—Adjusted Age-Specific Risk Rates for Cancer of the Penis in Uncircumcised Males*

Age Group x_i-x_{i-n}, yr	No. Alive at Age x_i	Estimated No. Alive at Midpoint of Interval	Adjusted Penile Cancer Risk Rate for Uncircumcised Men, 10^{-5} per Year	Expected No. of Penile Cancers
0-30	100,000	97,036	0.00	0.00
30-35	94,072	93,535	0.26	1.22
35-40	92,997	92,269	1.03	4.75
40-45	91,541	90,455	1.00	4.52
45-50	89,369	87,720	1.80	7.89

85+	13,168	6,584	17.33	5.71
Total				**166.15**

*Rates applied to the 1971 US life table.[5]

ing of penile cancer incidence in the entire population. This latter effect would not affect our analysis since we exclusively address the risk to the uncircumcised male and not to the entire male population. We believe the life-table analysis provides a reasonable estimate of the risk for cancer of the penis in uncircumcised males.

Populations, Predictions, and Hygiene.—These figures largely reflect the experience of the white majority of the US population. The lifetime risk may be greater for racial groups with higher incidence rates and mortality for this malignant neoplasm. For instance, American blacks suffer a 2.5-fold increased annual incidence[3]; their mortality may be as much as four times higher than that of whites.[11] It is not clear what component of this increased risk may be accounted for by lower circumcision rates.

Since the uncircumcised male is uniquely susceptible, virtually all of these cancers are preventable by neonatal circumcision. The number of lifetime incident cancers that could be prevented annually by circumcision can be estimated with birth statistics available for 1971. In that year, there were 1,822,910 recorded live male births.[12] If none had been neonatally circumcised, our analysis predicts that one in 600, or more than 3,000 would have penile cancer in their lifetimes.

It has been suggested that careful penile hygiene could provide a level of protection nearly comparable with that provided by circumcision. St John-Hunt[13] and Diddle[14] have indicated, however, that adequate penile hygiene among uncircumcised males in Western countries is in fact not observed on a population basis.

Considerations Other Than Penile Cancer

A decision regarding the value of circumcision may not be made solely on the basis of penile cancer risk. Other points of consideration include the greater incidence of balanitis and phimosis in uncircumcised males as well as the risks of adult circumcisions these conditions may necessitate.[1] In addition, there is a finite complication rate for neonatal circumcisions. Frequency of important nonfatal complications (primarily hemorrhage, infection, and trauma) ranges from 0.06% to 0.25% in the three largest studies published since 1953[15-17]; these studies involved more than 24,000 patients. The rates may be expressed alternately as 60 per 10^5 and 250 per 10^5, respectively, and are comparable to the lifetime risk for penile cancer estimated here for uncircumcised males.

Mortality as a complication of circumcision is rare. A review of the literature since 1953 yielded only two reports of circumcision-related deaths.[15,18] *Vital Statistics for 1971*[7] records no male deaths in categories[19] that include not only circumcision-related deaths but also those owing to complications and misadventures of prophylactic appendectomies and sterilizations, among others. These figures may underestimate the true circumcision-related morbidity and mortality owing to reluctance on the part of physicians and hospitals to report such incidents. Difficulties in assigning cause of death where multiple medical problems contribute may also be a factor.

Finally, arguments based on religious and social preference continue to play a major role. Such issues are not amenable to the cost vs benefit approaches that can be applied to the more medical aspects. We submit that the lifetime risk for penile carcinoma deserves inclusion among these many factors figuring in the controversy regarding circumcision. Further investigation is indicated in several areas. Specifically, dependable data regarding circumcision rates and firm definition of related complications and their frequencies are needed. Comparable figures for disease usually attendant to the uncircumcised state (such as complications owing to phimosis and balanitis) would also be helpful. However, given the many fronts on which the subject is being debated, it is likely that circumcision will remain a controversial topic.

Nonstandard Therapies in the Developmental Disabilities

Gerald S. Golden, MD

• The complexity of management issues with regard to developmentally disabled children has led to broad acceptance of a number of therapeutic approaches that purport to be effective for a wide range of problems. These are generally empiric in origin, and the efficacy of most of them cannot be supported by controlled research studies. In addition, there has been little or no investigation of potential or actual side effects. Acceptance of new therapies and validation of older approaches need to be based on appropriately designed, controlled studies.

(*Am J Dis Child* 134:487-491, 1980)

Developmentally disabled children present the professional therapist with a broad range of problems, including those of a cognitive, motor, behavioral, interpersonal, social, and familial nature. Because of the complexities involved in the development of management programs that will meet all of these needs, therapies purported to have a positive impact in all of these areas have great appeal. If they seem to be based on sound, scientific fact and if they seem to be free of obvious deleterious side effects, their acceptance is often rapid, complete, and uncritical.

Some of these therapies have become entrenched in clinical practice by many years of use. Generally, they have never been put to a critical, controlled trial. Other treatment methods are newer, and this article will review some of the most recent and most popular. This in no way implies endorsement of other treatments that are in common use but have never been adequately tested.

NONSTANDARD THERAPIES

As stated earlier, there are "standard" therapies that never have been adequately evaluated. The meaning of "nonstandard" is ambiguous, but all of these methods share certain characteristics, which will be used to formulate an operational definition. (1) They all are said to be based on biochemical or neurophysiologic theories, but these theories are not congruent with current concepts of function of the CNS. (2) They all purport to be extremely effective in a broad range of developmentally disabled children; often, the diagnostic criteria are poorly defined. (3) They are said to be incapable of causing harm. (4) There have been no adequately controlled studies published in major peer-reviewed journals. Publication is typically in nonreviewed journals, books, or lay publications. Case material is anecdotal, and a testimonial approach is used. (5) The therapies often have an emotional appeal, and studies that do not confirm effectiveness are attacked defensively.

The specific treatment modalities to be discussed are the following: (1) biochemically based therapies: megavitamins, orthomolecular mineral therapy, additive-free diet, hypoglycemia; (2) neurophysiologically based therapies: patterning, optometric training.

BIOCHEMICALLY BASED THERAPIES

Megavitamins

This therapy is an attempt to treat dysfunction of the nervous system not due to specific vitamin deficiency with extremely large doses of a number of vitamins. The origin is in the work of Hoffer and Osmond,[1] who postulated that schizophrenia was due to the accumulation of toxic metabolites formed by abnormal body metabolism. In 1960, Hoffer et al[2] identified the putative toxin as an abnormal metabolite of epinephrine and developed a treatment protocol initially using niacin, and then also adding ascorbic acid and pyroxidine hydrochloride. A theoretical article by Pauling[3] in 1968 discussed these concepts and led to the coining of the term "orthomolecular psychiatry," which is often used as a synonym for megavitamin therapy.

The following year, Cott[4] published an article consisting of six case reports that suggested improvement of the conditions of children diagnosed as schizophrenic when treated with large doses of niacinamide, ascorbic acid, pyridoxine, vitamin E, and pantothenate calcium. He also implied that the great majority of the children were hypoglycemic. Further publications[5,6] extended these concepts to learning disabled children and to those with behavioral disorders. The nutritional concept was further broadened to raise questions of abnormalities in balance of mineral intake. Claims of lack of potential toxicity of this treatment are made in all of the reports. There has been little else published in support of these theories.

The theoretical basis for megavitamin therapy is open to question, as has been fully discussed by Herbert.[7] These vitamins, in the human organism, are essential to life by definition. They have no primary function, but are cofactors; that is, they combine with enzyme proteins and thus activate the function of the enzyme. This is adequately carried out at levels close to the recommended minimum daily allowances. An excess of vitamins has no additional effects once the sites are saturated, although addi-

tional apoenzyme may be produced. It has also been shown that huge doses of vitamins may cause very high levels in blood, but increase the levels within the CNS little or not at all.[8] Vitamin deficiences exist, but produce clearly defined and well-recognized clinical syndromes.

It is fair to ask whether the empiric findings show megavitamin therapy to be useful, even if the hypothesis on which the treatment is based is incorrect. Hoffer and co-workers' results have not been confirmed by large studies.[9,10] The clinical reports written by Cott and involving children[4,6] are difficult to interpret. Two make reference to 500 children who have been treated, without specific data being provided. The other provides six narrative case reports. Case material is described in such a way that diagnoses of specific children are not clear. None of the requirements of a properly performed drug study are met; that is, there is no clear definition of patients, measurements, or methods of evaluation. No double blind, placebo, or other techniques to remove the observor bias were used. They are, therefore, essentially anecdotal and testimonial statements, without interpretable data.

A double-blind, placebo-controlled study of megavitamins was carried out by Arnold et al[11] with 31 children who exhibited hyperkinetic behavior. After a two-week treatment period, changes in a number of rating scales were ascertained and a decision made as to whether response to treatment (unknown to the evaluator) was good enough to continue, or whether a change to another therapy was needed. The two children who responded well were both in the placebo group. Pretest-posttest ratings by parents and teachers failed to show any significant differences in children of either group.

The issue of the potential toxicity of this therapeutic technique is being seriously raised.[7,12-14] Vitamins fall into two major groups, fat-soluble (vitamins A, D, E, and K) and water-soluble (all of the others, including niacin, ascorbic acid, and pyridoxine). The fat-soluble vitamins are stored in the body and are only slowly excreted. Both vitamins A and D have well-known, seriously life-threatening side effects when taken in large doses, and generally are not included in megavitamin regimens, although there has been a case report of severe vitamin A poisoning in a 4-year-old boy who received this therapy.[15]

There is some question as to whether or not vitamin E actually is a vitamin. Side effects of large doses are many, and include headaches, nausea, fatique, dizziness, blurred vision, decreased sexual function, sores around the mouth, gastrointestinal disturbances, muscle weakness, hypoglycemia, and a clotting factor deficiency. It may antagonize the effects of vitamin A, and cause a relative deficiency of vitamin K. In most instances, vitamin K does not seem to be part of the therapeutic plan.

The water-soluble vitamins are not stored in the body, and large doses are very rapidly excreted and essentially wasted. However, massive doses can cause unpleasant and potentially dangerous side effects. Niacin (or niacinamide) has produced skin flushing, itching, circulatory disturbances, cramps, liver damage, elevated blood glucose levels, elevated uric acid levels with gouty arthritis, peptic ulcers, skin pigmentation, cardiac arrhythmias, and nervous panic. It also may produce a relative deficiency of pyroxidine. No definite toxicity of pyroxidine has been found, but there is some suggestion that it causes enlargement of the liver in experimental animals.

Large doses of ascorbic acid may precipitate gout, cause kidney stones, produce scurvy in the newborn infants of mothers who take large doses or in adults who suddenly stop large dosages, and cause abdominal cramps and diarrhea. It may interfere with urine tests for diabetes and test for blood in the stools. Large doses also may neutralize the effect of therapeutically administered anticoagulants, and cause the destruction of most of the vitamin B_{12} in the diet. There have been reports of breakdown of RBCs in people with glucose 6-phosphate dehydrogenase deficiency, and crises in patients with sickle cell disease.

Therapy With Minerals

A number of minerals are recognized as being important in human nutrition, including copper, zinc, magnesium, and manganese. They, as is true for the vitamins, do not function independently, but as cofactors in enzymes or other proteins. Because of the very small amounts needed to maintain health, they are usually considered to be trace elements. Balanced diets provide more than enough of all of these substances.

Little has been written about the possible role of these substances in developmental disabilities, although this was suggested by Cott.[5] Hair samples from learning disabled children and controls were analyzed for 14 elements by Pihl and Parkes.[16] Results of discriminant function analysis showed that the two groups could be separated at the 98% level of accuracy by using values for five elements. Levels of cadmium, manganese, and chromium were increased in the learning disabled children, whereas levels of cobalt and lithium were decreased. Although not used as discriminators, levels of lead and sodium were also increased. The authors pointed out that their definition of learning disability was overly general. It should also be noted that control samples were obtained 2½ months after the clinical samples and were, therefore, not analyzed simultaneously.

Except for this study, the majority of clinical reports have been anecdotal. A new therapy has arisen and the diagnosis of deficiency is usually based on the analysis of the mineral content of the patient's hair. Hair analysis has been used to detect certain types of heavy metal poisoning in forensic pathology, but the relationship between the hair's content of these substances and general mineral metabolism is unknown. In addition, there are many problems with hair analysis. These include the lack of standardized washing procedures and the need to group hair content norms by hair color, the condition of the hair (growing, resting, shed), and the portion of the hair analyzed.[17] A single hair may represent two or three years in the life of the patient and have very different mineral content in different areas of the shaft.

The use of this therapy is new and toxicity data are scanty. As a general principle, the body's mechanism for ridding itself of excess quantities of minerals is poor, and they tend to accumulate. Some, such as iron and

copper, have clearly defined, major toxic effects when ingested in excess. Zinc, a commonly used element in these therapies, was considered harmless, but has recently been reported to cause low levels of serum copper and abnormalities in both RBCs and WBCs.[18] It will be many years before the safety of the other minerals in these doses can be proved.

Additive-Free Diet

Feingold[19] published a book in 1975, in which he presented the hypothesis that hyperactivity and learning disabilities in children are due to natural salicylates in food and to certain food colorings and additives. The hypothesis states that hyperactivity is due to a nonimmunologic (nonallergic) response to these substances in children susceptible because of genetic variations. The mechanism involved the "innate releasing mechanism" of the brain. This theory has many problems. Which brain mechanism is implicated is unclear because the terminology is not standard, but Feingold possibly means the reticular activating system. Diagnostic criteria for hyperactivity and learning disability are not well defined, and the statement that these syndromes have increased in frequency in recent years is unsupported by any data. The genetic argument is not supported by data.

Assuming that the author made an accurate empiric observation despite the faulty hypothesis, it can be asked if properly designed clinical studies have confirmed the usefulness of this diet. An uncontrolled study of 15 children from Australia reported that ten parents were "quite certain" and three were "fairly certain" that the child improved on the diet and relapsed promptly with dietary infractions.[20]

The first controlled study was that of Conners et al.[21] A double-blind, crossover design that used a baseline diet, a control diet, and the additive-free diet was instituted with 15 children. The observers were teachers and parents who used standardized rating scales. When comparing the test diet with the child's baseline diet, both teachers and parents saw improvement and scored differences were at the $P < .05$ level of significance. Comparing the test diet with the control diet, teachers reported significant improvement, but parents did not. Although the test diet-control diet differences were significant, the mean scores represent only a small change in behavior. The author recommended a cautious approach in interpretation due to the small sample size and the inconsistent results.

A different approach was used by Williams et al.[22] Twenty-six children were organized into four groups based on administration of active (stimulant drugs) or placebo medications and of control cookies or challenge cookies that contained a number of food colorings. Results were determined by teacher and parent checklist ratings. Stimulant medications were clearly more effective than the diet in the reduction of hyperactivity; diet may have been of some slight use in from three to eight of the children, depending on the criteria used. Children receiving placebo possibly showed more activity with the challenge cookies than with the control cookies. The authors concluded that the diet may have use in certain children, but not as a general treatment.

Two other results of this study were of interest. The parents believed that the diet was effective when the children were also receiving medication, whereas the teachers found the diet to be the most effective in children not receiving stimulant drugs. The other finding that requires further study is that there was no exacerbation of hyperactivity after dietary lapses in those children who seemed to improve on the diet. For these reasons, the results are inconsistent but interesting enough to be pursued, and this may permit detection of a subgroup of responsive children.

The largest and most carefully designed study to date is that of Harley et al.[23] The investigators removed all food from the houses of the participating families, and supplied everything during the course of the study. All of the family members ate the experimental diets. Food was supplied for family guests and holidays, as well as to the entire class if any child in the room had a birthday. Several experimental and distracting procedures were used to obscure dietary changes. Observations included teacher ratings, objective classroom and laboratory observations, parental ratings, and psychological tests.

The results of this study provided no support for the hypothesis that the additive-free diet was effective. The parents who reported some improvement in the conditions of children on the diet only did so if the experimental diet followed the control diet. The reverse order showed no differences. Thirteen mothers rated their child's condition as improved on this diet sequence, whereas six mothers rated it as worse on the test diet. In no case did laboratory or classroom data confirm these findings. Interviews with the parents after the study showed that none could identify the sequence and timing of the diet crossovers used.

In a second phase of this study, the nine boys whose scores showed the best "response" and who were available to participate were placed on a strictly controlled, additive-free diet for 11 weeks.[24] Using a double-blind protocol, both placebo and additive-containing challenge foods were given with multiple crossovers. Measurements consisted of parental and teacher rating scales, classroom observation, and neuropsychological testing. The challenge with materials containing artificial color had no adverse effects. This does not support the hypothesis, and certainly does not support the concept that a dietary infraction rapidly causes a recurrence of abnormal behavior that can last for several days.

In summary, the well-controlled studies fail to document any improvement in the behavior of children on the additive-free diet. The positive results of uncontrolled studies can be ascribed to psychological factors.

The question of potential harm is obviously not as much of a concern as with the megavitamin and orthomolecular mineral approaches. Initial data showed borderline ascorbic acid levels in the diet, but this does not seem to be an important problem since salycylate-containing foods (many fruits and vegetables) are no longer restricted. There are four points that must be weighed in a cost-benefit analysis. The first is that the only successful way to assure implementation of the diet is to use it for the entire family. This change in

eating pattern and style may be unacceptable for other family members and lead to friction, focusing hostility on the patient. The second issue is that of the time, effort, and expense involved in trying to buy additive-free foods and in preparing foods that cannot be purchased without additives. If both parents are employed, the time commitments may be impossible to meet.

The third issue is that of the artificial and highly restricted nature of the diet and the inability of the child to join his peers for snacks, parties, or even regular meals. The developmentally disabled child has great difficulties with social interaction, peer group acceptance, and self-esteem. None of these are alleviated by the dietary restrictions. Finally, many of the medications that might be necessary for the child (anticonvulsants, antibiotics, antihistamines, etc) contain the forbidden substances. Resistance by the parents to giving drugs may develop and medical care compromised.

Hypoglycemia

The relationship between low blood glucose levels and learning disabilities was also suggested by Cott.[5] This has become a popular diagnosis for a host of neurologic and behavioral symptoms, with little or no documented, published experience. There are two important issues concealed within this "common" problem that is treated with such dietary strategies as low carbohydrate-high protein diets and frequent feedings. The first is that the diagnostic techniques are often improperly used. A proper glucose tolerance test requires adequate preparation of the patient with an appropriate diet before the glucose load is administered, a properly sized load, and blood specimens taken for at least five to seven hours. Correct interpretation of the laboratory results is obviously required, and the normal drop in blood glucose level should not be overinterpreted. The patient must show both a low blood glucose level and symptoms (pallor, diaphoresis, tachycardia) concurrently.

The most important fact is rarely discussed. If the patient is truly hypoglycemic, this is not necessarily a benign condition that should be treated with diet.[25] Careful evaluation and a number of metabolic tests are required to determine which of the many causes of hypoglycemia is involved. The conditions range from the annoying to the life-threatening. Some are genetic in origin and have implications for genetic counseling. Treatment ranges from surgery through drugs to diet. These evaluations are rarely if ever performed by those centers frequently using dietary treatment based on this diagnosis. The long-range effects of these diets on growth and development are not known.

NEUROPHYSICALLY BASED THERAPIES

Patterning

This is one of the most commonly applied and widely known of the neurophysiologic treatment techniques. The method, developed by Doman et al,[26] was based on theories of Temple Fay. The method attempts to move the abnormal brain through a normally sequenced developmental pattern by sensory stimulation and the imposition of passive movement on the patient. No well-controlled experimental studies were published, and the widespread popularity of the technique is based largely on testimonial evidence. The technique is time-consuming, and may require a large number of volunteer "therapists" to come to the child's house each day and assist with the patterning. The demands and time schedules are rigidly imposed, and failure to show developmental progress may be blamed on deviations from the routine.

In this treatment modality, the ideas of organization and reorganization of the CNS are inconsistent with current knowledge.[27] Twenty-five children, who ranged in age from 2 to 16 years and who suffered from a variety of neurologic conditions, were studied by Harel et al.[28] They were placed in a patterning program and followed up for 1½ years. At the end of this period of time, the parents were asked to give subjective evaluations of their child's progress. In nine of 20 cases, they believed that there had been "significant" improvement, and in another nine of 20, "some" improvement. Evaluation by standardized tests, however, showed great improvement in only one case, and some improvement in six. This clearly illustrates the problems with observer bias. In addition, there was no untreated control group. The authors pointed out that therapy required three to four hours per day for each child, and that eight families reported major stresses in family life around the issue of the heavy burden of the therapeutic program.

Sparrow and Ziegler[29] studied institutionalized, seriously retarded children. There were 15 subjects in each of three groups: patterning, motivational control, and no treatment. The study was continued for one year and there were a variety of outcome measures. All three groups showed some improvement in performance during the course of the study, but there was no difference in degree of improvement for the group that received patterning treatment, the group that received placebo treatment, and the group that received the usual treatments offered at the institution. The study thus failed to confirm any positive effect for the technique as applied to this group of children.

The potential harm of the method is not physical, but rather is its great expense and the investment of time by the parents and volunteers. This method may also hold out false hopes for the families and delay their ability to come to some accomodation with the severity of the child's deficit.

Optometric Training

The techniques subsumed under this term are many,[30] but are based on the theory that learning disabilities are primarily due to abnormal visual perceptual and sensory-motor coordination processes, and that they can be improved with various types of visual and neurologic organizational training. Two issues raised by this approach are important to examine. First, there is no evidence that reading disability involves the eyes, eye movement, or eye balance. Children with severe visual or oculomotor handicaps learn to read normally if the material is presented with appropriately sized type. The second issue is that current research is moving away from a perceptual abnormality model of dyslexia, and now emphasizes the areas of language disability, amnestic

syndromes, and more complex deficits in cognitive processing.[31] There is no reason to assume that ocular training will affect any of these abnormalities. Controlled data are virtually nonexistent.

As with patterning, the harm comes from the time and expense of a course of treatment with no proven benefit. In addition, it may distract the family from the key issue, that of appropriate special education.

COMMENT

The therapies discussed all attempt to offer specific, universally effective therapies for complex problems that are global and that vary from patient to patient. As indicated, controlled data are almost entirely lacking, and when present are equivocal. Risks range from increased expense and distraction from more important issues, to potentially severe physical harm.

When faced with the task of evaluating a new therapy, a fairly standard approach can be used. The first question to be asked is whether the theory on which the therapy is based is consistent with current concepts of the anatomy, physiology, and biochemistry of the CNS. Then, there must be a cost-benefit analysis that balances the evidence that the treatment is effective against the potential, recognized or theoretical, for harm.

Effectiveness should only be accepted if based on properly designed studies. This requires the same rigorous approach as would be built into any laboratory study, and the design should include appropriate controls, adequate measurement techniques, and a large, clearly defined, and fully described experimental group. It should always be remembered that the burden of proof is on the proponents of the treatment. They must prove efficacy. Critics of the technique need not prove noneffectiveness, but should insist on positive data from the proponents.

The question of the ethics of denying the treatment to the control group in studies is often raised. In fact, it is unethical in most instances not to carry out the controlled study. Not only may it fail to show a therapeutic effect, it is always possible that it may show the treatment to be harmful or worse than no treatment at all. The history of medicine is full of such examples.

It should never be assumed that any treatment is harmless. This is, of course, true of biochemical treatments, but also true of behavioral therapies. Patients must be followed up for a long period of time to search for delayed problems. Also, for this reason, short-term studies cannot be used to justify long-term treatment. The lack of signs of toxicity of a drug given over a three-week period does not in any way prove that it will be harmless if given for months or years. This is of particular concern with the use of massive doses of vitamins and minerals.

The cost-benefit analysis must also take into consideration monetary strains on the family, time commitment, and the effect of these on the other family members. The effect of the therapy on the child's ability to function in peer group settings outside of the therapy situation cannot be neglected. Treatment must never be allowed to distract from the core issues of special education, social growth, individual adjustment, and family interactions.

The scientific approach to scientific problems cannot be replaced by untested hypotheses leading to undocumented therapies. Bronowski[32] stated that, "Magic is a technology, technology without science." Each person must decide whether to practice science or magic.

This investigation was supported in part by Bureau of Community Health Services grant MCT-00024-014.

CSF Neurotransmitter Studies

An Infant With Ascorbic Acid-Responsive Tyrosinemia

Joan W. Stoerner, MD; Ian J. Butler, MB, FRACP; Frank H. Morriss, Jr, MD; R. Rodney Howell, MD; William E. Seifert, Jr, PhD; Richard M. Caprioli, PhD; Eugene W. Adcock III, MD; Susan E. Denson, MD

• A female newborn infant with Marfan-like habitus experienced lethargy and hypothermia associated with tyrosinemia that was not corrected by the administration of ascorbic acid at 50 mg/day but that subsequently responded to ascorbic acid at 500 mg/day. Cerebrospinal fluid analysis for neurotransmitter metabolites showed elevated concentrations of homovanillic acid and 5-hydroxyindoleacetic acid when the child was symptomatic and normal concentrations after successful ascorbic acid therapy. These observations suggest that a high level of tyrosine in serum can affect the metabolism in the brain of dopamine and serotonin.

(*Am J Dis Child* 134:492-494, 1980)

Transient neonatal tyrosinemia (serum tyrosine level > 4 mg/dL) is a common finding in premature infants. A high-protein diet, decreased activity of the enzyme parahydroxyphenylpyruvic acid oxidase, and a low ascorbic acid intake lead to transient impairment in the oxidation of tyrosine.[1] The administration of low doses of ascorbic acid orally or parenterally can abolish the tyrosinemia.[2] Decreased motor activity, lethargy, and poor feeding have been associated with elevated tyrosine levels.[3,4] Several follow-up studies have indicated that neurological and intellectual development are normal in children who had neonatal tyrosinemia.[5-7] However, Mamunes et al[8] have described intellectual deficits in full-term infants with transient neonatal tyrosinemia.

This report describes a premature infant with phenotypic features of Marfan's syndrome who had hypothermia, lethargy, and poor feeding associated with an elevated serum tyrosine level that was unaltered by the recommended dose of ascorbic acid but that responded to large doses of ascorbic acid. Cerebrospinal fluid neurotransmitter metabolite concentrations were abnormal during the period of symptomatic tyrosinemia, but they returned to within normal limits when serum tyrosine concentrations became normal. The CSF neurotransmitter metabolite findings in this individual patient with transient tyrosinemia are important considerations in the unresolved question of the potential harmfulness of transient tyrosinemia.

REPORT OF A CASE

This female patient weighed 1,940 g at birth, an appropriate weight for her gestational age of 35 weeks. The Apgar scores were 6 at one minute and 7 at five minutes. Her parents were a 20-year-old, gravida 2, para 1, abortus 1 mother, and a 21-year-old, nonconsanguineous father, both of whom had negative family histories for features of Marfan's syndrome. Physical examination of the infant disclosed plagiocephaly, long and thin extremities, an arm span 3.6-cm greater than her length, arachnodactyly, slender feet with flexed toes, and mild pectus excavatum. Her ophthalmologic examination showed no abnormalities. She had no evidence of congenital heart disease. A chest roentgenogram showed 11 pairs of ribs and tapered clavicles. The infant's immediate postnatal course was complicated by hyperbilirubinemia caused by A-O blood group incompatibility and sepsis that was suspected but not confirmed when she became hypothermic and tachypneic.

Urine tests to rule out homocystinuria revealed a positive nitrosonaphthol test at 2 weeks of age. Chromatographic analysis of amino acids in her serum detected a mildly elevated tyrosine level of 4.9 mg/dL during the third postnatal week (Table 1). Prolonged neonatal tyrosinemia was suspected at age 7 weeks when her serum tyrosine level increased to 12.9 mg/dL although her diet contained less than 4 g of protein per kilogram per day. A trial of oral ascorbic acid, 50 mg/day, for four days was given with no substantial change in the serum tyrosine level. The potency of the ascorbic acid was not tested. At age 10 weeks, she had gastroenteritis that was treated with clear liquids, and her serum tyrosine level declined to 2.9 mg/dL.

At 12 weeks of age, after resuming a regular diet for age without vitamin supplementation, she had poor feeding, hypothermia, and lethargy. Blood, urine, and CSF cultures obtained to evaluate suspected bacterial sepsis were sterile. The serum tyrosine concentration was 18.0 to 23.9 mg/dL, and the serum phenylalanine concentration was 3.3 mg/dL. A lumbar puncture was performed to obtain CSF for analysis of neurotransmitter metabolites.

From the Departments of Pediatrics (Drs Stoerner, Morriss, Howell, Adcock, and Denson), Neurology (Dr Butler), and Biochemistry (Drs Seifert and Caprioli), Medical School, the University of Texas Health Science Center at Houston.

Reprint requests to Department of Pediatrics, University of Texas Medical School, 6431 Fannin St, Houston, TX 77030 (Dr Morriss).

The serum tyrosine level decreased sharply after cessation of oral feedings and the institution of intravenous (IV) fluid therapy. An oral diet containing less than 5 g of protein per kilogram per day was started; simultaneously, the patient was treated with ascorbic acid, 500 mg/day, orally for one week. The serum tyrosine concentration decreased to 6.6 mg/dL and subsequently remained less than 5 mg/dL when she was receiving a regular diet without supplemental ascorbic acid. At 15 months of age, when the patient's diet was normal, concentrations of serum amino acids and CSF neurotransmitter metabolites were again analyzed.

No further episode of lethargy or hypothermia has occurred. She has continued to demonstrate Marfan-like features with neither ophthalmologic nor cardiac abnormality, and she has had mild hip contractures. Her growth was appropriate for the first 2 years; during her third year, she exhibited greater than normal increases in height and arm span. Her psychomotor development was normal at 1 year of age, as assessed by the Denver Developmental Screening Test and the Gesell Developmental Schedule. At age 26 months, her speech was delayed; but by age 3 years, her speech was developing normally.

LABORATORY METHODS

In the two samples of CSF obtained from the lumbar subarachnoid space of the patient and in CSF samples from 16 control subjects, homovanillic acid (HVA), 5-hydroxyindoleacetic acid (5-HIAA), and 3-methyoxy-4-hydroxyphenylethylene glycol (MHPG) were measured by a quantitative gas chromatographic-mass spectrometric method.[9] The CSF for HVA, 5-HIAA, and MHPG measurements was collected in glass tubes containing 2 mg/mL of ascorbic acid, was placed on ice, and was stored at −80 °C. Control subjects were children of similar age to the subject when studied who had lumbar punctures for investigation of neurological problems including cerebral palsy, psychomotor retardation, and neuromuscular and myoclonic disorders. Concentrations of amino acids in serum were analyzed by automated ion-exchange chromatography.[10]

RESULTS OF NEUROTRANSMITTER METABOLITE STUDIES

The basal levels of HVA and 5-HIAA seemed substantially elevated when the child was lethargic and hypothermic, and the serum tyrosine level was elevated. A year later, tyrosine concentration was normal in the serum, CSF concentrations of HVA and 5-HIAA had decreased to normal, and the MHPG value was normal (Table 2).

Table 1.—Serum Tyrosine and Phenylalanine Concentrations*

Age, wk	Tyrosine, mg/dL	Phenylalanine, mg/dL	Comments
2	3.8	1.4	. . .

COMMENT

Three aspects of this infant's course are especially noteworthy: (1) her abnormal phenotype, (2) the response to larger-than-usual doses of ascorbic acid, and (3) the CSF neurotransmitter studies. In premature infants, the maximum serum tyrosine level usually occurs by the third week of life; concentrations then spontaneously return to normal by the sixth week.[1,11] Although ascorbic acid deficiency has not been demonstrated, administration of ascorbic acid at 50 to 100 mg/day usually corrects the disorder if the protein intake does not exceed 5 g/kg/day. In this patient, the administration of much larger doses of ascorbic acid were associated with resolution of the tyrosinemia after usual doses had failed. Although the serum tyrosine concentration had declined to 8.6 mg/dL while the patient was maintained on IV dextrose infusion prior to the start of ascorbic acid therapy at 500 mg/day, there was no return to high serum tyrosine values with the resumption of oral protein intake as had occurred during the 12th week when ascorbic acid was not given.

The clinical symptoms of sepsis and CNS depression in neonates with tyrosinemia have been described but not understood. Although the inhibition of

myelination has been shown in newborn rats with tyrosinemia,[12] the effect of tyrosine on the developing human nervous system is unknown. The role of abnormal levels of neurotransmitters or their metabolites in the brain in the presence of elevated serum amino acids is particularly intriguing.

The aromatic amino acid tyrosine is a precursor in the biosynthesis of the catecholamine neurotransmitters dopamine, norepinephrine, and epinephrine.[13] Systemic administration of tyrosine to rats for short periods will increase brain levels of tyrosine and 3, 4-dihydroxyphenylalanine (DOPA), the immediate precursor of dopamine.[14] Systemic administration of levodopa for short periods to mice will increase dopamine, have no effect on norepinephrine, and decrease serotonin levels in the brain.[15] Levodopa administered systemically to rats will transiently increase brain levels and accelerate turnover of norepinephrine.[16] In rat-brain slices, levodopa is converted to dopamine, which displaces serotonin from neurons,[17] an observation that supports other evidence that systemic administration of levodopa will deplete brain serotonin reserves.[18]

The basal levels of HVA and 5-HIAA in the lumbar CSF reflect the biosynthesis, storage, and degradation in the brain of dopamine and serotonin, respectively.[19] Levels in the CSF of MHPG, the main metabolite of norepinephrine, are believed to indicate brain levels of that neurotransmitter.[20] The HVA and 5-HIAA values in the CSF from this patient obtained on two occasions suggest that a high level of tyrosine in serum can affect the metabolism of dopamine and serotonin and potentially norepinephrine. Unnatural amino acids, as precursors of false neurotransmitters, affect normal neurotransmitter metabolism in the brain.[21] In addition, the natural precursor amino acids in abnormal concentrations will affect normal neurotransmitter biosynthesis.[22] The elevated levels of HVA and 5-HIAA in the CSF could indicate extremely high levels of these acidic metabolites in the brain, which could directly and adversely affect brain function.[23]

The above experimental data indicate that tyrosine increases brain dopamine levels and HVA production and that serotonin, displaced from neurons by excess dopamine, is then further degraded to 5-HIAA. Although this would be consistent with our results, there could be other explanations for these changes in CSF metabolites, such as an increased degradation of both neurotransmitters. On the first occasion that the CSF neurotransmitter metabolites were measured, the child had received ascorbic acid four weeks previously. Thus, another possible explanation for the increase in CSF metabolites of dopamine and serotonin could be the stimulation by L-ascorbate of the hydroxylation of the aromatic amino acids tyrosine and tryptophan at the rate-limiting step in dopamine and serotonin biosynthesis.[24] However, this in vitro effect was not seen in rat brain in which ascorbic acid caused an increase in norepinephrine but a decrease of dopamine in areas of the brain.[25] The importance of the results, however, is to indicate the potential role of a perturbation of catecholamine and indoleamine neurotransmitters in the developing brain because of an elevation of tyrosine in the serum. Whether abnormal concentrations of neurotransmitter metabolites are present in the CSF from patients with other forms of tyrosinemia unassociated with Marfan-like habitus is presently not known.

Acute Caffeine Overdose in the Neonate

William Banner, Jr, MD, Peter A. Czajka, PharmD

• **To our knowledge, the clinical course of acute caffeine poisoning in neonates has not been previously reported. Three full-term infants manifested CNS irritability after the parenteral administration of large doses of caffeine and benzoate sodium injection in the delivery room for respiratory depression. The infants received caffeine in doses that ranged from 36 to 136 mg/kg. On arrival in a regional newborn center, they exhibited one or more of the following symptoms: tachypnea, fine tremor of the extremities, opisthotonus, tonic-clonic movements, and nonpurposeful jaw and lip movements. The overdose of caffeine produced a clinical picture that suggested neonatal seizures and prompted therapy with anticonvulsants. A fourth infant (premature) attained a high plasma caffeine concentration, but this infant's symptoms were altered by intraventricular hemorrhage. The combination of caffeine overdose and perinatal asphyxia may precipitate or increase seizure activity in the neonate. Recognition of the potential toxic effects of caffeine overdose should guide patient care and stimulate further study to establish appropriate use of caffeine in the newborn infant.**

(*Am J Dis Child* 134:495-498, 1980)

Although acute caffeine poisoning in adults has been reported since 1883,[1] the effects of caffeine overdose in newborn infants are apparently unrecorded in the medical literature. Caffeine and other methylxanthines, such as theophylline and theobromine, have many effects, including diuresis, smooth muscle relaxation, skeletal muscle stimulation, myocardial stimulation, and CNS stimulation. The stimulation of the medullary respiratory center increases the rate and depth of respiration and sensitizes this center to carbon dioxide.[2] This effect has been exploited in the treatment of apnea of prematurity. Both theophylline and caffeine are useful in the management of recurrent episodes of apnea, when underlying pathology has been excluded.[3,4]

Neonatal exposure to caffeine occurs as a result of maternal transmission through breast milk[5] and from therapeutic use in the delivery room or nursery. Even though the use of caffeine in the delivery-room management of apnea seems limited and controversial, a contemporary textbook of neonatology[6] states that caffeine is "well tolerated . . . [and] large doses may be given without serious ill effects."

We studied four neonatal cases of caffeine poisoning after administration of an injectable preparation of caffeine. After the diagnosis of caffeine poisoning in the index patient, three additional cases were discovered during a three-week surveillance of admissions to the local newborn center. Plasma caffeine concentrations were measured in three patients with a previously described high pressure liquid chromatographic assay adapted for caffeine.[7]

REPORT OF CASES

Case 1.—The patient was a 2,660-g, full-term girl born to an 18-year-old primagravida. The pregnancy was uneventful and labor was spontaneous. Delivery was complicated by cephalopelvic disproportion. A low-forceps delivery was unsuccessfully attempted, so the infant was delivered spontaneously. At birth, the Apgar score at 1 minute of age was 5 and the infant required vigorous physical stimulation and oropharyngeal suction. An intramuscular injection of 94 mg/kg of caffeine was

given as a solution of caffeine and benzoate sodium. The Apgar score at 5 minutes of age was 10. The child had no difficulty until 18 hours of age, when "arching of the back" developed. Dexamethasone and phenobarbital were given intramuscularly. She remained opisthotonic for 12 hours and so was transferred to the University of Tennessee Newborn Center, Memphis.

On admission to the Center, her temperature was 38.2 °C; pulse rate, 180 beats per minute; respirations, 68/min; and systolic blood pressure, 110 mm Hg. The infant was hypertonic, with opisthotonic posturing and clenched fists, and had coarse tremors of all extremities. She was awake, crying, and extremely irritable. Arterial blood examination on admission showed a pH of 7.46; P_{CO_2}, 13 mm Hg; and P_{O_2}, 44 mm Hg. In addition, the hematocrit value was 62.5%; hemoglobin, 20.2 g/dL; WBCs, 17.9 × 10^3/cu mm, with 1% band forms, 73% neutrophils, 17% lymphocytes, 8% monocytes, and 1% myelocytes. The serum calcium concentration was 9.9 mg/dL; sodium level, 145 mEq/L; potassium level, 3.7 mEq/L, and glucose oxidase paper strip test, 90 mg/dL. A lumbar puncture at that time was traumatic. Cultures of the blood and CSF were made and therapy with ampicillin sodium and gentamicin sulfate begun. Ultimately, all cultures showed no growth. The baby's opisthotonic posturing persisted through the next day despite therapy with sodium bicarbonate and intravenous (IV) diazepam. She was given nasogastric feedings, a small amount of IV fluids, and chloral hydrate for her persistent tremors. At age 5 days, the infant's condition had begun to improve, but she still had minimal opisthotonic posturing; her plasma caffeine concentration was 31.9 μg/mL. At 7 days of age, the patient was asymptomatic and the caffeine concentration was 10.4 μg/mL. A repeat lumbar puncture showed ten WBCs, which were 100% mononuclear, 116 RBCs, a protein concentration of 75 mg/dL, and a glucose concentration of 53 mg/dL. An EEG and computerized tomographic (CT) scan of the brain were normal. The child was discharged after two weeks with no seizure activity.

Case 2.—The patient was a 3,760-g full-term infant born to a 20-year-old gravida 2, para 1. The pregnancy was complicated by diabetes mellitus without prenatal care. In addition, the mother had preeclampsia during labor. Maternal medications given during delivery included magnesium sulfate, furosemide, hydralazine, chlorothiazide, and reserpine. Information about the delivery was not complete, but it was a difficult, low-forceps delivery with a nuchal cord. The Apgar score at 1 minute of age was 0. The baby received 68 mg/kg of caffeine as caffeine with benzoate sodium by umbilical vein catheter while in the delivery room. At 2 hours of age, the baby became lethargic and appeared to be in mild respiratory distress. While receiving oxygen, he was given 4 mg of dexamethasone, 0.11 mg of atropine, and another dose of caffeine (68 mg/kg), all intramuscularly. Subsequently, the infant was transferred to the University of Tennessee Newborn Center.

On arrival, his temperature was 37.4 °C; pulse rate, 180 beats per minute; respiratory rate, 82/min; and systolic blood pressure, 74 mm Hg. The infant was jittery and hyperirritable, with posturing of the extremities and purposeless movements of the mouth. Results of admission arterial blood measurements gave a pH of 7.28, P_{CO_2} of 36 mm Hg, and P_{O_2} of 39 mm Hg while receiving 94% oxygen. The WBCs were 36.0 × 10^3/cu mm, with 23% band forms, 25% neutrophils, 32% lymphocytes, 10% monocytes, 2% eosinophils, and 6% metamyelocytes. The serum calcium concentration was 8.5 mg/dL; sodium concentration, 138 mEq/L; potassium concentration, 3.8 mEq/L; and glucose oxidase paper strip test, 90 mg/dL. The CSF had RBCs, 2,830/cu mm, and WBCs, 40/cu mm, 60% as mononuclear forms, a total protein concentration of 87 mg/dL, and a glucose concentration of 68 mg/dL. Gram stains and cultures of the CSF and blood ultimately showed no growth. Shortly after admission, the infant was treated with 2 mg/kg of IV tolazoline hydrochloride. Arterial blood values immediately improved to a pH of 7.49, P_{CO_2} of 24 mm Hg, and P_{O_2} of 144 mm Hg. During the next 24 hours, the pH remained elevated with a decreased P_{CO_2}, but improving oxygenation allowed the infant to be placed in room air. The symptoms of hyperirritability persisted. These were considered to represent seizure activity and were managed with administration of phenobarbital and intermittent administration of diazepam. The irritability continued for three additional days. Thereafter, the symptoms gradually diminished and caffeine poisoning was suspected. During this period of improvement, further studies showed a normal CT scan of the brain and a normal EEG. The patient was discharged and followed up as an outpa-

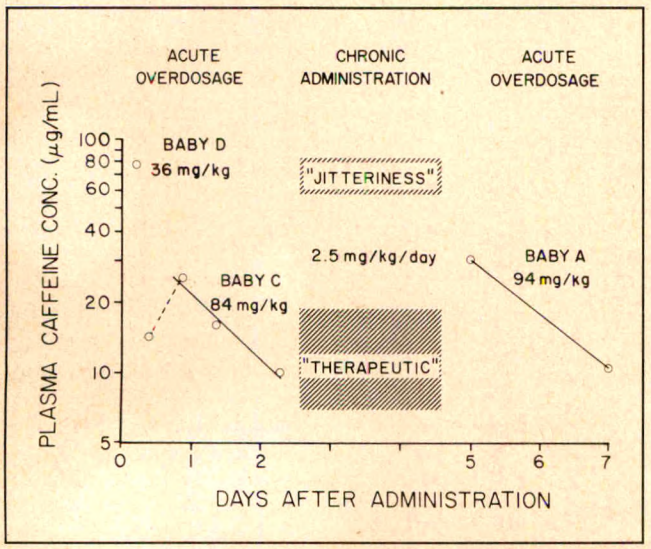

Fig 1.—Comparison of plasma caffeine concentrations in neonates (cases 1, 3, and 4) in whom severe toxicity developed after an acute overdosage, and those who experienced mild toxicity after long-term administration in pharmacokinetic study.[8]

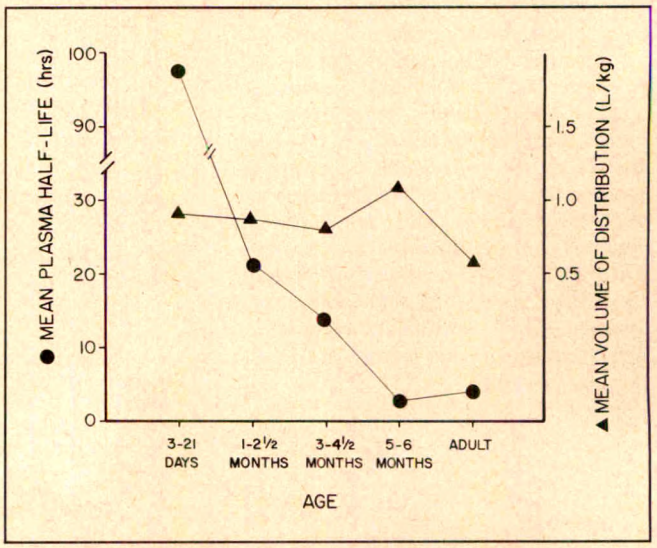

Fig 2.—Comparison of pharmacokinetics of caffeine in infants[15] and adults.[16]

tient. Plasma caffeine concentrations were not determined since this was the index patient. Three months after discharge, the child did not exhibit any further seizure activity and was doing well.

Case 3.—The patient was a 2,960-g, full-term infant born to a 21-year-old primagravida. The presentation was frank breech, but a vaginal delivery was performed. The delivery of the infant's head was delayed for ten minutes and a nuchal cord was noted. The mother received a total of 75 mg of IV meperidine hydrochloride prior to delivery. After delivery, the baby had a normal pulse rate, but had no spontaneous respiration. He was intubated, ventilated, and given an unknown dose of naloxone hydrochloride intramuscularly and 84 mg/kg of caffeine as caffeine with benzoate sodium intramuscularly. Thereafter, the infant began to have spontaneous respirations and was subsequently transferred to the University of Tennessee Newborn Center.

On admission, the temperature was less than 34.4 °C, the pulse rate was 104 beats per minute, the respiratory rate was 48/min, and the systolic blood pressure was 88 mm Hg. Neurologic examination showed upward deviation of both eyes and alternating periods of hypertonicity and hypotonicity. Results of arterial blood examination were as follows: pH, 7.24; Pco_2, 26 mm Hg; Po_2, 120 mm Hg. The serum calcium concentration was 9.0 mg/dL; sodium concentration, 142 mEq/L; potassium concentration, 5.4 mEq/L; and glucose oxidase paper strip test, 90 mg/dL. The infant was given IV fluids and phenobarbital. Plasma caffeine concentrations were determined at 8.5, 20.0, 32.5 and 57.5 hours of age and were reported as 13.7, 26.1, 16.7, and 10 μg/mL, respectively (Fig 1). Additional evaluation included a normal CSF analysis results and a normal CT scan. The infant continued to have rigidity, tonic movements, and purposeless lip movements for four days. The patient was discharged after ten days of therapy with phenobarbital (5 mg/kg/day). There was no further evidence of seizure activity.

Case 4.—The patient was a 1,730-g infant born to a 32-year-old gravida 3, abortus 1, at 32 weeks' gestation. She was delivered by cesarean section for a breech presentation and partial abruption. Apgar scores were 2 and 4 at age 1 and 5 minutes, respectively. The infant required oxygen by mask and was given 0.5 mL of caffeine with benzoate sodium (36 mg of caffeine per kilogram) intramuscularly. She was then transferred to the University of Tennessee Newborn Center for evaluation and management.

On admission, the infant was bradycardic and hypotensive, with severe acidosis and almost no respiratory effort. She was resuscitated with a good response initially. At 5 hours of age, the plasma caffeine concentration was 79.9 μg/mL. At 12 hours of age, the baby's vital signs suddenly deteriorated. A clinical diagnosis of intracranial hemorrhage was made, which was later confirmed by CT scan. The infant received volume expanders and packed RBCs. She required ventilatory support for two weeks and exhibited seizure activity for four days. Ultimately, the infant survived, with severe neurologic sequelae. No other caffeine determinations were obtained because it was believed that the large amount of plasma and blood given the infant would alter the caffeine concentrations.

COMMENT

The newborns described here were given caffeine doses that ranged from 36 to 136 mg/kg. All doses greatly exceeded the 10 mg/kg loading dose of caffeine suggested by Aranda et al[8] for the treatment of recurrent neonatal apnea. Assuming a cupful of coffee to contain 100 mg of caffeine, 25 to 95 cups of coffee would provide to an adult (70 kg) the amount of caffeine comparable to the acute overdose in these infants.

It is difficult to distinguish clearly the contribution of perinatal hypoxia to the symptoms of caffeine overdose. Central nervous system irritability after perinatal hypoxia is typically manifest by tonic posturing or clonus of one or more of the extremities; eyelid blinking, nystagmus, or ocular deviation; orofacial grimacing or automatisms; autonomic dysfunction; and apnea.[9] Information on the manifestations of caffeine poisoning is derived from the few case reports of acute poisoning in children and adults. Bren et al[10] reported a 7-week-old infant with tonic posturing, fixed upward gaze, and irritability after the ingestion of strong tea. Sullivan[11] reported a case of caffeine poisoning in a 12-month-old child who had "coffee ground" emesis, tachycardia, agitation, twitching of the extremities, hyperglycemia, ketonuria, and hypertension. These symptoms, which were associated with a serum caffeine concentration of 46 μg/mL, occurred nine hours after an ingestion of an unknown amount of caffeine in the form of 100-mg tablets (No-Doz). Similar symptoms were observed in a 3-year-old child who ingested 78 mg/kg of caffeine also in tablet form.[12] We are aware of a 2-year-old boy who was treated at our institution and survived a massive ingestion of a combination of extracts of buchu, uva ursi, triticum, and zea, and caffeine (Tri-Aqua; caffeine, 92 mg/tablet). The child's symptoms consisted of hematemesis, tachycardia (170 beats per minute), and coarse muscle fasciculations of the extremities and abdomen, with alternating states of stupor and hyperirritability. He achieved a peak plasma concentration of caffeine of 190 μg/mL at 12 hours postingestion. Furthermore, the symptoms of our first three cases were compared to those reported in older infants and children, as follows: neonates showed hyperirritability, opisthotonus, hypertonicity alternating with hypotonicity, upward ocular deviation, rigidity, and purposeless lip movements; whereas, the older children showed hyperirritability, tonic posturing, stupor alternating with agitation, upward ocular deviation, muscle fasiculations, hypertension, tachycardia, hyperglycemia/ketonuria, and emesis/hematemesis. Symptoms of CNS irritability occurred in both groups. However, the hypertension, hyperglycemia, ketonuria, and hematemesis that occurred in children were not apparent in our younger patients. The symptoms observed in our patients may not have been exclusively due to caffeine poisoning; however, the caffeine would probably exacerbate any previous irritability and confuse the clinical presentation.

Adverse effects of neonatal caffeine therapy were noted in a pharmacokinetic study in which transient jitteriness developed in three newborn infants with plasma caffeine concentrations of 58.4 to 84 μg/mL.[8] Case 4 had concentrations in this range, but two of our babies exhibited serious symptoms at much lower concentrations (Fig 1). A review of four adult fatalities[13,14] associated with caffeine overdosage shows a wide range of postmortem blood caffeine concentrations (1,040.0, 158.5, 106.0, and 79.0 μg/mL). This discrepancy may reflect

differences between short-term vs long-term exposure or interpatient sensitivity to the toxic effects of caffeine. It is possible that there is a predisposition to caffeine-induced toxicity in asphyxiated neonates.

Particular care should be taken in administering caffeine to newborn infants because the elimination of caffeine is greatly impaired in neonates.[15] In fact, the rate of elimination of caffeine does not approach the rate observed in adults until the age of 5 to 6 months (Fig 2). Therefore, caffeine administered to neonates is likely to result in prolonged effects, when compared with children and adults. Another consideration with the use of injectable caffeine with benzoate sodium is the potential risk of bilirubin displacement by benzoate sodium.[17] The use of injectable diazepam in the neonate is generally avoided because it contains benzoate sodium 50 mg/mL; whereas, the injectable caffeine preparation used in these cases contains benzoate sodium 125 mg/mL.

The four cases reported here demonstrate that large doses of caffeine are not universally well tolerated by newborn infants and may be potentially dangerous. We suggest that caffeine be reserved for the infant with recurrent apnea when infectious, metabolic, and neurologic causes have been excluded. This precludes its use during the immediate postpartum period. When caffeine is indicated for recurrent apnea, the dosage and therapy should be monitored and evaluated by measurement of plasma caffeine concentrations, as described by Aranda et al.[8] In this way, the toxicity of a potentially useful drug may be avoided.

Between the presentation and publication of this article, a similar case was reported in *Pediatrics* (64:254, 1979).

This study was supported in part by National Institutes of Health grant T32-GM07533.

Sheldon B. Korones, MD, and the staff of the University of Tennessee Newborn Center gave assistance. James F. Beattie, MD, and John F. Williams, MD, brought the index patient to our attention.

Newborn Screening in New York State

In 1964 New York State implemented a PKU (phenylketonuria) Screening Program for all newborns. In 1974 additional conditions were added to the screening program, as listed below.

Since the inception of the screening program, the following number of children have been identified as having these conditions:

	No.	Incidence
PKU	215	1:16,700
Galactosemia	24	1:73,000
Branched chain ketonuria	2	1:600,000
Histidenemia	6	1:160,000
Homocystinuria	2	1:480,000
Adenosine deaminase deficiency	1	1:1,200,000
Sickle cell disease	158	1:4,300

As of December 1, 1978, congenital hypothyroidism was added to the mandated screening program. The expected incidence of congenital hypothyroidism is about 1:4,400.

New York State Department of Health (September 1979).

Falsely Normal Radionuclide Scans for Osteomyelitis

Gary R. Fleisher, MD; Jan E. Paradise, MD; Stanley A. Plotkin, MD; Spencer Borden IV, MD

• Three children are described with osteomyelitis confirmed by roentgenogram, blood culture, bone culture, and/or histologic findings. None had an abnormal technetium scintigram. Despite the lack of falsely normal bone scans for osteomyelitis reported in the literature, our cases demonstrate the importance of instituting antibiotic therapy on the basis of clinical suspicion since no single nonsurgical procedure can be relied on to make a diagnosis of osteomyelitis.

(*Am J Dis Child* 134:499-502, 1980)

In childhood osteomyelitis, prompt institution of therapy can increase the likelihood of complete recovery. However, early diagnosis may be difficult since laboratory tests and roentgenograms frequently do not distinguish osteomyelitis from cellulitis, septic arthritis, toxic synovitis, or trauma. The ESR and WBC count may be normal and, if elevated, are not specific for bone infection. In a series by Dich et al,[1] culture of the blood yielded an organism in only 57% of the patients with subsequently proved osteomyelitis. Capitanio and Kirkpatrick[2] observed soft-tissue changes early in the course of some cases of childhood osteomyelitis, but roentgenograms are often normal until seven to ten days after the initial visit.

Recent attention has focused on the scintigraphic detection of osteomyelitis in children. It has been stated that scintigraphy can establish the diagnosis of osteomyelitis soon after the onset of symptoms and before roentgenographic changes become apparent.[3-8] Although radionuclide scanning has also been a useful technique for this purpose at our hospital, we recently encountered three children with osteomyelitis who had normal bone scans early in the course of their illness. This report emphasizes the importance of instituting antibiotic therapy on the basis of clinical suspicion since no single nonsurgical procedure can be relied on to make a diagnosis of osteomyelitis.

REPORT OF CASES

Case 1.—A 12-year-old boy was admitted to the Children's Hospital of Philadelphia for evaluation of left hip pain of two days' duration. He appeared mildly ill, and his temperature was 39.2 °C. Palpation of the abdomen elicited mild, diffuse tenderness, but there was no rebound tenderness, mass, or organomegaly. Bowel sounds were normally active. The area of the left hip and sacroiliac joint was tender without erythema, warmth, or edema. Internal and external rotations of the left hip were limited by pain. The remainder of the physical examination showed no abnormalities.

Laboratory studies disclosed the following values: hemoglobin, 9.8 g/dL; hematocrit, 30%; and WBC count, 10,400/cu mm, with 81% neutrophils, 16% lymphocytes, and 3% monocytes. The ESR (Wintrobe) was 60 mm at one hour, and electrophoresis indicated hemoglobin A. Results of urinalysis were normal. Roentgenograms of the chest, left hip, sacroiliac joint, and lumbosacral area of the spine showed no lytic lesions or periosteal elevation.

Aspiration of the left hip joint yielded 0.5 mL of clear synovial fluid, with 60 WBCs per cu mm, and no bacteria were seen on Gram's stain. The initial therapy for a presumed osteomyelitis was nafcillin sodium. The initial blood culture and a repeated blood culture 24 hours later had growths of *Staphylococcus aureus*, which were sensitive to nafcillin. The joint culture and all subsequent blood cultures were sterile.

A radionuclide scan using technetium Tc 99m pyrophosphate (Fig 1, left) was normal on the second hospital day, and a repeated bone scan and roentgenograms were normal on the fifth hospital day. An intravenous pyelogram showed an extrinsic compression of the bladder on the left side, and a film of a barium enema showed a mass that impinged on the sigmoid colon. These findings were interpreted as consistent with retroperitoneal lymph node enlargement.

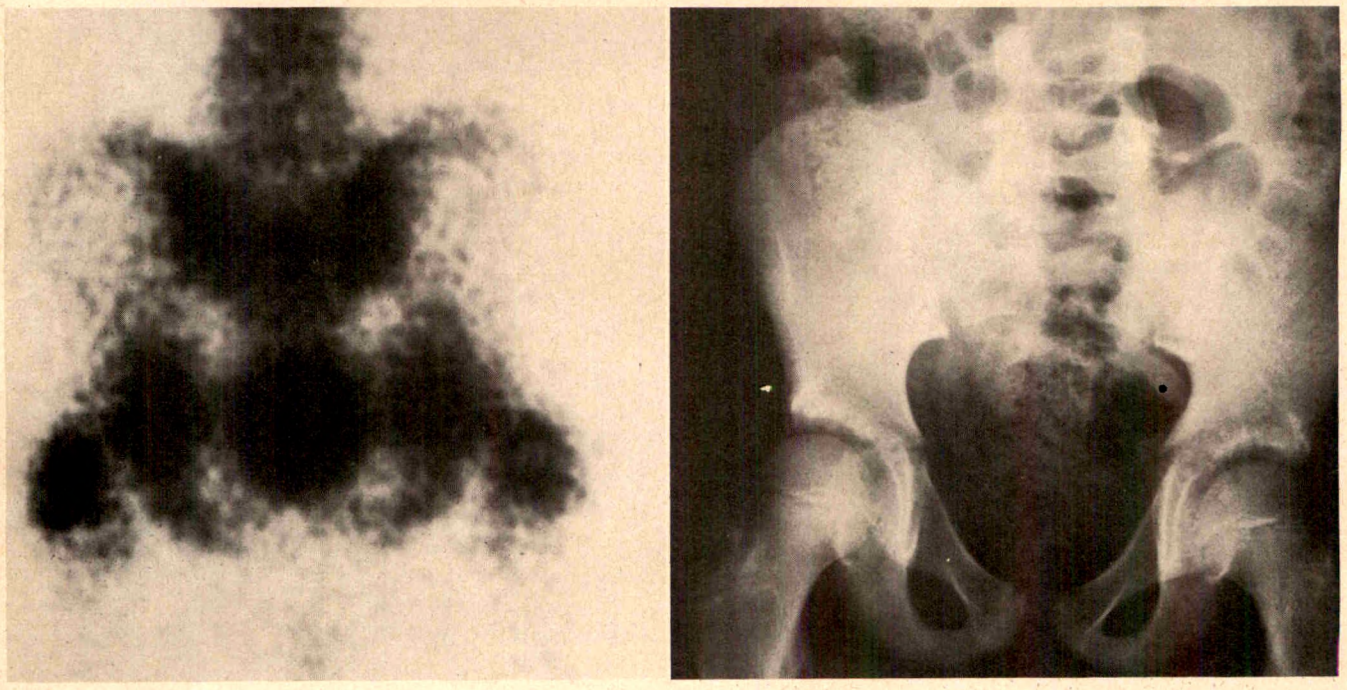

Fig 1.—Case 1. Left, Normal bone scintigram. Right, Roentgenogram on 17th hospital day, showing lytic lesion in ilium adjacent to left sacroiliac joint.

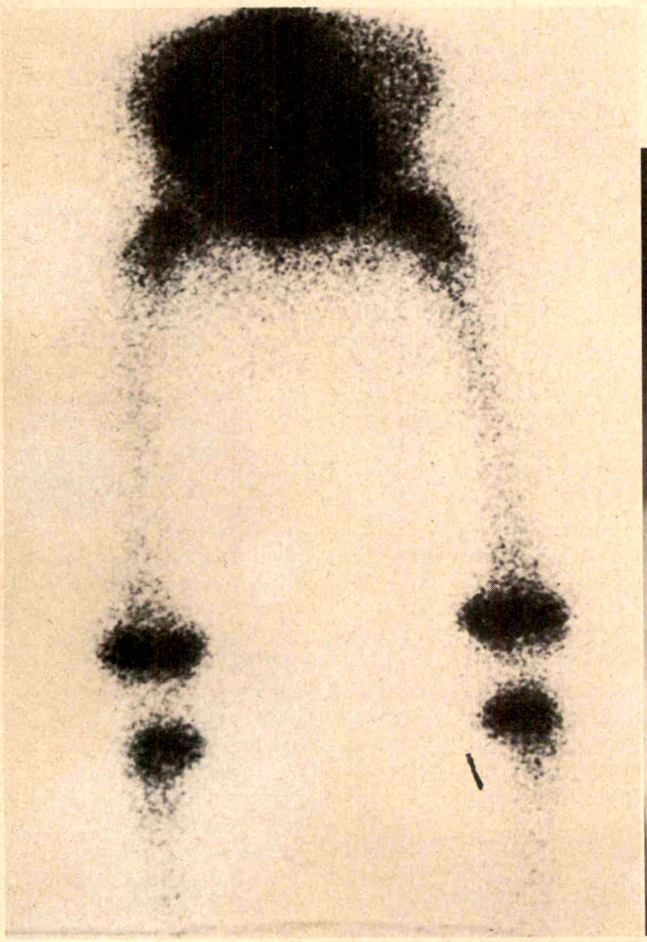

Fig 2.—Case 2. Left, Normal bone scintigram. Right, Roentgenogram on 21st hospital day, showing lytic lesions of proximal left femur. (Periosteal elevation along margin of left femur was visible on actual roentgenogram but is difficult to see on this reproduction.)

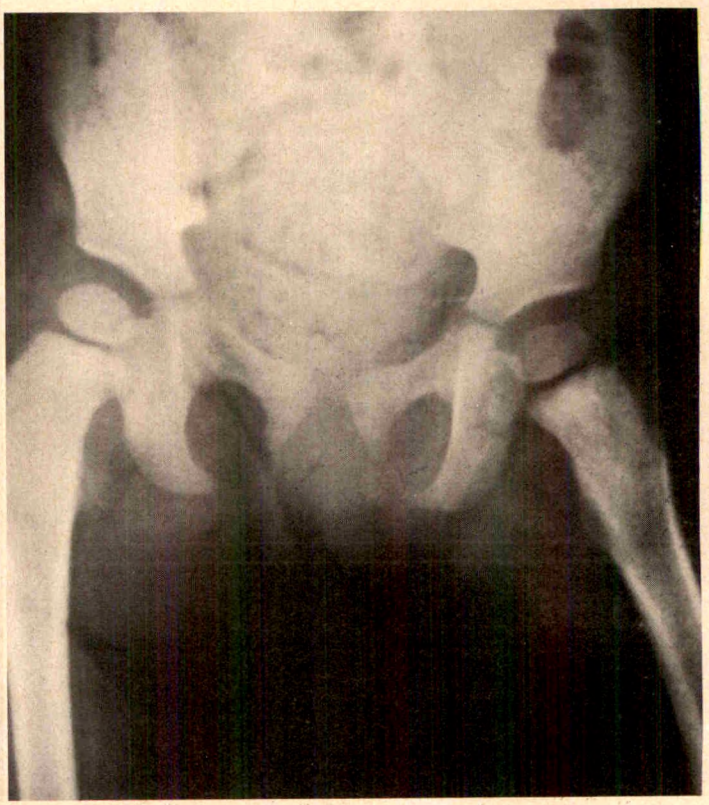

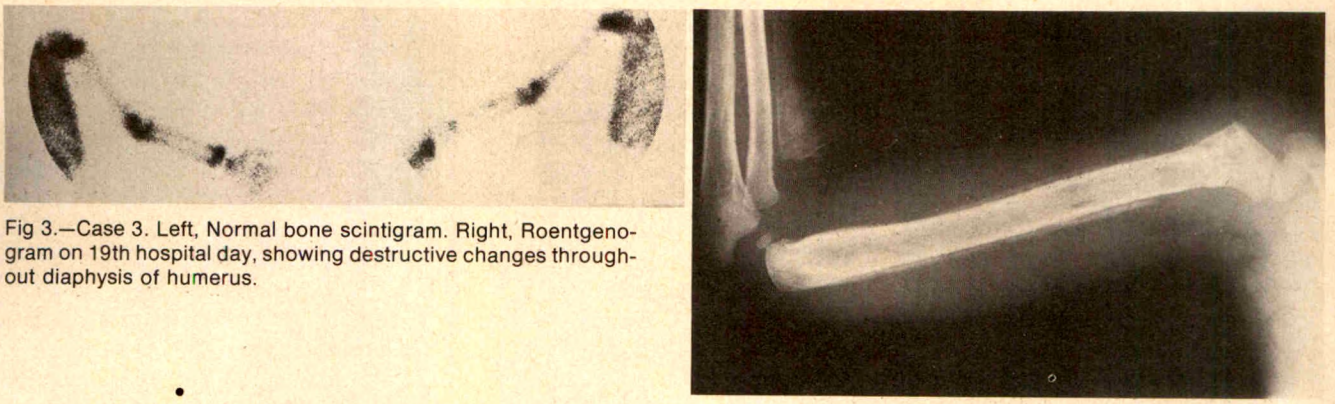

Fig 3.—Case 3. Left, Normal bone scintigram. Right, Roentgenogram on 19th hospital day, showing destructive changes throughout diaphysis of humerus.

On the 17th hospital day, a roentgenogram (Fig 1, right) showed a lytic lesion in the ilium adjacent to the left sacroiliac joint. At surgical exploration, there was a necrotic area in the ilium, pus in the sacroiliac joint, and an abscess cavity contiguous to this joint. The infected area was debrided and drained. Results of pathologic examination were consistent with acute osteomyelitis. Aerobic and anaerobic cultures of the pus and necrotic bone were sterile. The child received six weeks of nafcillin therapy and was discharged in good health. Repeated roentgenograms showed sclerosis at the site of the lytic lesion in the ilium.

Case 2.—A 22-month-old female infant was admitted to the Children's Hospital of Philadelphia, with a limp of two days' duration. She appeared mildly ill, and her temperature was 38.3 °C. She maintained her left lower extremity rigidly extended and resisted movement. Passive range of motion was full, but it elicited considerable pain. There was no point tenderness, swelling, erythema, or warmth of the spine, pelvis, hips, or femurs. The remainder of the physical examination showed no abnormalities.

The values for the laboratory studies were as follows: hemoglobin, 11.7 g/dL; hematocrit, 30%; and WBCs 12,000/cu mm, with 2% band forms, 70% neutrophils, 12% lymphocytes, 12% monocytes, and 1% eosinophils. The ESR (Wintrobe) was 46 mm at one hour, and electrophoresis showed hemoglobin AA_2. Roentgenograms of the chest, lumbosacral spine, sacroiliac joint, left hip, and left lower extremity were normal.

The child remained febrile on the second hospital day. A radionuclide scan using technetium Tc 99m pyrophosphate (Fig 2, left) was normal. Aspiration of the left hip joint under fluoroscopy yielded 0.5 mL of clear fluid that was Gram- and culture-negative. On the third hospital day, oxacillin sodium therapy was begun when the blood cultures taken on admission to the hospital had growths of *S aureus*. A gallium scan was normal. Ambulation returned gradually from the seventh to 14th hospital day. A roentgenogram (Fig 2, right) of the left femur on the 21st hospital day showed destructive bone changes in the left proximal femur and periosteal elevation along the shaft, both of which were consistent with osteomyelitis. She recovered uneventfully after six weeks of oxacillin therapy.

Case 3.—A 3-year-old boy with sickle cell anemia was admitted to the Children's Hospital of Philadelphia with right arm pain and fever of three day's duration. He appeared to be in considerable pain, and his temperature was 39 °C. His right forearm and wrist were swollen and tender. The results of the rest of the physical examination were normal.

Laboratory studies gave the following results: hemoglobin, 8.0 g/dL; hematocrit, 25%; and WBC count, 24,000/cu mm, with 9% band forms, 75% neutrophils, 8% lymphocytes, and 8% atypical lymphocytes. The ESR (Wintrobe) was 48 mm at one hour. A roentgenogram showed diffuse, soft-tissue swelling of the right arm.

The child was treated initially with ampicillin sodium. On the second hospital day, chloramphenicol sodium succinate and gentamicin sulfate were added to the patient's therapy when a Gram-negative rod was detected in the initial blood cultures. The organism was later identified as *Salmonella* C_1, which was sensitive to ampicillin, and the chloramphenicol and gentamicin treatments were discontinued. A technetium bone scan (Fig 3, left) was normal.

A needle aspiration of the patient's distal right humerus was performed on the fifth day. This yielded no pus, and cultures were sterile. On the 19th hospital day, a roentgenogram (Fig 3, right) of the child's right arm showed destructive changes throughout the diaphysis of the humerus, most likely the result of extension of infection originating at the metaphysis.

On the 35th day of ampicillin therapy, a second needle aspirate of the patient's humerus yielded bloody fluid containing many neutrophils. *Salmonella* C_1, sensitive to ampicillin, grew from a culture of this fluid, and chloramphenicol was added to the patient's therapy. Surgical drainage of the patient's distal humerus on the 43rd hospital day produced 10 mL of sterile pus from the subperiosteal and intramedullary spaces, which was sterile on culture.

After 57 days of ampicillin and 23 concurrent days of chloramphenicol therapy, the patient was discharged home with good mobility and no tenderness of his right arm. His ESR was 4 mm at one hour, and roentgenograms disclosed healing osteomyelitis and callus formation around a pathologic fracture.

COMMENT

Radionuclide scanning is generally recognized as a useful technique in the early diagnosis of osteomyelitis.[3-8] Although ordinary roentgenograms may not detect a destructive bone medullary lesion until it has reached a size of 1 to 1.5 cm and has resulted in a loss of 30% to 50% of bone matrix, scintigraphy often demonstrates variations in bone metabolism that may precede even the soft-tissue roentgenographic abnormalities.

In 1966, DeNardo[8] studied 18 patients with suspected osteomyelitis. The strontium scintigram was abnormal in all of the 13 confirmed cases, although five of them had normal roentgenograms. No patient had a falsely normal scintigram.

Recent experience with children has confirmed the reliability of radionuclide scanning. Letts et al[7] studied 20 children with suspected osteomyelitis who had normal roentgenograms. Of the 15 children with focally increased uptake of radionuclide by bone, 14 proved to have osteomyelitis, and one had a leukemic bone deposit. None of

the five children with normal bone scans had osteomyelitis. Treves et al[4] described eight children with infections of long bones, and Trauner and Connor[5] described two children with sacroiliac osteomyelitis, all of whom had diagnostic bone scans. Seventy of 71 children described by Gilday et al,[6] and all of the 34 patients reported by Majd[3] had radionuclide scans confirming the diagnosis of osteomyelitis.

Our three patients had proved osteomyelitis in spite of normal bone scans. A definite diagnosis was delayed in the first child with sacroiliac osteomyelitis because he was initially thought to have either an intra-abdominal abscess or a septic arthritis of the hip[9,10] and because two scintigrams, performed after four and seven days of symptoms, failed to demonstrate any abnormality. The recovery of *S aureus* from the blood, the appearance of bony destruction on roentgenograms, and the histologic findings of the bone biopsy specimen eventually confirmed the diagnosis.

In the second child, osteomyelitis was suspected initially because of the hip pain and limitation of motion in spite of normal results of a joint fluid examination. The positive blood cultures for *S aureus* and the later roentgenographic changes confirmed the clinical impression. Since bone aspiration yielded no pus, open surgical drainage and biopsy were not performed.

The isolation of *Salmonella* from the blood of the third child, who had sickle cell anemia and a painful swollen arm, strongly suggested osteomyelitis early in the hospitalization; however, a scintigram on the fifth day of symptoms was normal.[11] The positive culture from bone, the later roentgenographic abnormalities, and characteristic histologic findings verified the clinical diagnosis.

Review of the literature indicates that radionuclide scanning is a reliable method for the detection of osteomyelitis. Only one falsely normal scan occurred among 129 children with osteomyelitis reported by several authors.[3,6,7] An explanation for the occasional normal bone scan early in the course of osteomyelitis has been postulated.[12-14] It is suggested that inflammation spreading from within the marrow space may interfere with the blood supply to the metaphysis. Subsequent scintigrams may be abnormal, with involvement of the cortex and periosteum.

The exact role of scintigraphy in the diagnosis of osteomyelitis needs further definition. Our cases demonstrate that, on occasion, the bone scan does not show increased uptake in confirmed infections. The possibility of falsely normal scintigraphy emphasizes the importance of instituting antibiotic therapy, after cultures are taken, on the basis of a strong clinical suspicion of osteomyelitis.

Trauma and Child Abuse

The Importance of the Medical Record

Gerald Solomons, MD

• **A chart audit was undertaken to ascertain the content and quality of documented information present in medical records of patients with traumatic injuries seen in a tertiary care hospital. Of the records of children younger than 6 years of age with a diagnosis of fracture, burn, contusion, or intracranial injury seen in the inpatient or outpatient services during a one-year period, 60% contained inadequate data on which to determine retrospectively if the medical diagnosis of child abuse was ever considered. The medicolegal implications of this are discussed.**

(*Am J Dis Child* 134:503-505, 1980)

Because of the increased incidence of reporting of child abuse and neglect, the health professional is appearing more frequently in court. The conduct and testimony of the medical witness in court have been the subject of several articles and audiovisual materials,[1-4] but the medical record has not been examined critically for content and quality. Many physicians, particularly interns and residents, have been appalled at the lack of information present in their patients' records after these documents, and they, have been subpoenaed. Juvenile court judges and attorneys have also complained of the lack of documentary evidence corroborating the verbal testimony of many of the professional witnesses. Cases have been dismissed because of lack of such evidence.

Of all the reported cases of child abuse in Iowa, a mere 3% are reported by physicians.[5] Because of this failure of health professionals to report, many state laws now include penalties such as fines and/or imprisonment; but despite these and the increase of information in professional journals and the lay press, there has not been a substantial increase in physician reporting.

Since 1976, 35 states have decreed criminal or civil penalties for failure to report child abuse.[6] In some states, the health professional may be liable for "the damages proximately caused" from failure to report, and the hospital record may be the evidence on which litigation is based.

The California Supreme Court decision in the Landeros case[5] allows litigation for malpractice if a full investigation for child abuse is not carried out for a patient with a diagnosis of suspected abuse. According to Zimmerly,[7] there are now two cases on record where parents accused of murder or negligence in the death of a child have brought malpractice action against the physician involved, claiming that lack of medical care rather than physical abuse caused death. Both actions failed, but there may be similar attempts in the future.

Many physicians are insensitive to the need to report the possibility of physical abuse in cases of trauma. There are several reasons. The commonest is ignorance of the law, its purpose, procedures, and penalties. Some physicians are just antagonistic towards it, viewing the law as an infringement on the rights of the individual. Many are erroneously frightened of being sued despite their immunity from civil and criminal liability. Excessive time in court; inadequate community programs for reported families, and disruption of the doctor-patient relationship are other explanations given for the physician's reluctance to "become involved." Irrespective of the reason, physicians cannot ignore their legal obligations of performing a comprehensive evaluation, reporting the case if they are suspicious of abuse, and supporting their decision by adequate documentation. This chart audit was undertaken to ascertain the content and quality of documented information present in

medical records of patients with traumatic injuries seen in a tertiary care hospital.

METHODS

Records of all patients younger than 6 years of age with a diagnosis of fracture, burn, contusion, or intracranial injury seen in the inpatient or outpatient services of University of Iowa Hospitals and Clinics, Iowa City, between July 1, 1975, and June 30, 1976, were reviewed. To determine retrospectively if the diagnosis of child abuse had been considered in trauma cases, the medical records were reviewed for the presence of four criteria. These criteria are considered to be mandatory and the minimal amount of information necessary. The four mandatory items were: (1) history of the injury; (2) description of the injury; (3) documentation of previous injuries or accidents; and (4) compatibility or incompatibility between the history given and the injuries sustained. The latter was based on an assessment of all the information in the record and was either obvious, stated, or implied.

If any of the just-mentioned four criteria were absent, the record was considered to be inadequate. The records were also evaluated subjectively for the quality of the information contained in the four criteria.

RESULTS

There were 161 cases of fractures, burns, contusions, and intracranial injuries that were seen at University of Iowa Hospitals and Clinics in children younger than 6 years of age during a one-year period. Five records could not be located, leaving 156 charts available. Of these visits, 25 were for elective repair or follow-up of a previous condition. Five cases reported as child abuse were not included. The 126 remaining case records were reviewed (Table 1).

Adequacy of Information

According to the aforementioned criteria, 35 of 62 (56%) cases of fractures, seven of 18 (39%) cases of burns, 23 of 27 (85%) cases of contusions, and 11 of 19 (58%) cases of intracranial injury were considered to have inadequate information on retrospective examination of the medical records to determine the presence or absence of child abuse. It was impossible to determine from these records if that diagnosis had even been considered.

Table 1.—Trauma Cases of Children Less Than 6 Years Old

Recorded Status	Fractures	Burns	Contusions	Intracranial	Total
Elective follow-up	7	13	. . .	5	**25**
Abused	4	. . .	. . .	1	**5**
Not located	. . .	. . .	. . .	. . .	[5]*
Reviewed	62	18	27	19	**126**
Total available	**73**	**31**	**27**	**25**	**156**

*Not counted in total of available charts.

Table 2.—Description of Injury by Category of Trauma

	Fractures	Burns	Contusions	Intracranial	Total, No. (%)
Basic	1	. . .	2	. . .	**3** (2)
General	51	16	21	18	**106** (84)
Detailed	10	2	4	1	**17** (13)
Total	**62**	**18**	**27**	**19**	**126**

The overall number of cases in the total sample of 126 with inadequate information was 76 (60%). It is worth noting that patients with contusions, the most common injury sustained in physical child abuse, had the highest percentage of inadequate records.

Subjective Evaluation of the Quality of the Information

History.—The history of the injury is obviously most important. It varied from a one-word description "fall" to the detailed "3 foot fall from dresser to carpeted floor while being diapered." Ideally, where there is a suspicion of abuse, the parents should be questioned separately and a conflict or change in the stories should be noted.

Description of the Injury.—The records varied from a basic statement of "multiple bruises," to a detailed description of number, size, location, and appearance of all lesions, including drawings. Only 13% were so precisely described (Table 2).

This is the one criterion over which the physician does have complete control. The written record often has more credibility than a photograph of poor quality. The description of the injury receives a great deal of emphasis in court because of its importance in determining the severity, extent, and method by which the injury was sustained.

Documentation of Previous Injuries or Accidents.—This item was often left out but its need is apparent. Even if this episode of trauma was not considered as possible abuse, a history of several previous injuries or noxious ingestions during a short period of time might support the decision to report this as a case of neglect. Neglect is a reportable condition in 47 states and the District of Columbia.[6]

Compatibility Between History and Injury.—This was often obvious or implied from the circumstances of the injury, eg, automobile accident, playground injury, etc. On occasion, there was a statement that history and injury were compatible if child abuse was initially suspected and then excluded after evaluation. Only when the decision was made to report the case as child abuse was there a statement in the record that the history and injury were at variance or incompatible. In the majority of records, the descriptions of history and injury were so cryptic that no determination of compatibility or incompatibility could be determined.

COMMENT

From the aforementioned results, it would seem that the majority (60%) of records of traumatic injuries of children younger than 6 years who were seen in this hospital contain inadequate data on which to determine retrospectively if the medical diagnosis of child abuse was ever considered. Unfortunately, the court's decision is most often based on the information contained in that record. It is possible that the appropriate questions were asked and satisfactory answers were given, but they were not recorded; and

such omission can be critical when litigation occurs or disposition of a case is decided.

Too often, the history of the injury was cryptic: "Fall from second story window." "Fall down stairs." "Fell from car." "Pulled coffeepot on him." Little attempt was made to determine the height of the fall, the presence of a carpet on the floor to cushion the impact, or the reason for an infant to be at an open window. Despite medicolegal emphasis on careful description of all traumatic lesions, only 13% were precisely described.

If the history and the injury are not definitively described, the compatibility between history and injury is also in doubt. Incompatibility is probably the most important criterion on which to base a medical decision to report suspected abuse. Ambiguity in this crucial factor can be hazardous to the patient who is still in jeopardy, as well as to the physician who may be guilty of malpractice or failure to report because of lack of clarity or imprecision in the record. On July 1, 1978, the Iowa law regarding abuse of children was amended to give this definition of physical abuse: "any nonaccidental physical injury, or *injury which is at variance with the history given of it,* suffered by a child as the result of the acts or omissions of a person responsible for the care of the child." This in itself is sufficient reason for a written statement regarding compatibility.

Records were inadequate to determine if child abuse was considered in the diagnosis in 60% of the cases. This is far too high a figure, particularly in a university teaching hospital with an active educational program and a committee for child abuse and neglect.

There is a need for a simple protocol for all cases of trauma that specifically details the following: the manner in which the injury occurred; a description of the injuries, with diagrams; a statement regarding compatibility of history and injury; and a list of previous injuries.

The focus of this article is on child abuse. However, even if this diagnosis is excluded, many cases of trauma may still have possible legal consequences for the patient (damages), and the physician (malpractice). The content of the medical record would be equally important.

In the present climate of litigation and public awareness of child abuse, the physician must realize the necessity for accurate recording. It is readily acceptable that documentation of known cases of suspected abuse need to be precise, but it could be argued that evaluation and documentation on unsuspected cases need not be so meticulous. The Landeros case is a classical example of such faulty logic. The lack of suspicion of the physician at the time of examination may be due to an inadequate history or an inadequate workup. There is now enough written in the professional literature to set the standard for medical competence in this area, and all physicians will have to meet that standard. Therefore, the need for precise documentation in all cases of childhood trauma is now necessary because of the health professionals' vulnerability in this regard.

Familial Pulmonary Atresia

Its Occurrence With a Ventricular Septal Defect

Joseph A. DiChiara; Daniel R. Pieroni, MD; Robert L. Gingell, MD; Robin M. Bannerman, DM; Peter Vlad, MD

• To our knowledge, this is the first reported case of pulmonary atresia with a ventricular septal defect that occurred in a father and his son. A multifactorial mode of determination that resulted from an interaction between genetic predisposition and environmental factors was assumed, since the family history did not show other members with congenital heart defects. Based on the background and on information from the multifactorial theory of inheritance, a counseling plan was formulated for these parents. A similar approach is recommended for the many surgical survivors of previously uncorrectable complex congenital heart defects as they approach reproductive age.

(*Am J Dis Child* 134:506-508, 1980)

Successful surgical correction of complex cyanotic congenital heart defects has created a patient population that is reaching child-bearing age.[1] Concern has been raised about the risk of cardiovascular malformations in the progeny of these patients. The opportunity to document recurrence of a defect in the first generation offspring has been particularly difficult in the face of previously uncorrectable and lethal lesions.

We studied a father and his son, both with pulmonary atresia and a ventricular septal defect. After review of the literature, we concluded this to be the first time the defect had been reported in a father and son, neither of whom had surgical correction. It supports the theory that recurrences of complex lesions are possible and that genetic counseling will be essential for the surgical survivors of previously fatal cardiac defects.

REPORT OF CASES

CASE 1.—A 2,400-g boy, born spontaneously at home to a 24-year-old gravida 3 para 2 mother, was admitted to a community hospital, where he was treated for pneumonia. He was subsequently transferred to the Intensive Care Unit of the Children's Hospital of Buffalo because of respiratory distress and progressive cyanosis. Evaluation showed the child to have pneumonia, atelectasis, and a pneumothorax. Despite respiratory improvement over the next five days, the child continued to be severely hypoxic. Because of continued cyanosis and the onset of a murmur, cardiac consultation was obtained.

The cardiovascular evaluation disclosed a pale, cyanotic infant with a right thoracotomy tube, a pulse rate of 150 beats per minute, and a blood pressure in both arms of 70/20 mm Hg. The precordium was relatively quiet to palpation. The first heart sound was normal, and the second heart sound was single. A grade 3/6 pansystolic murmur was detected at the second-left interspace, and there was no diastolic murmur. An apical gallop was easily audible. The liver was palpated 3 cm below the right costal margin. All peripheral pulses were bounding.

The ECG showed combined ventricular hypertrophy. Chest roentgenogram showed a large heart shifted to the left. There was atelectasis of the right-lower lobe and an infiltrate in the right-upper lobe. Although no pneumothorax was present, interstitial emphysema was observed. With the child breathing 80% oxygen, the arterial Po_2 was 25 mm Hg, the Pco_2 was 29 mm Hg, and the pH was 7.5. The echocardiogram showed a large aorta overriding the ventricular septum.

Cardiac catheterization revealed bidirectional ventricular shunting, with equal ventricular pressures. No obstruction was recorded across the aortic valve. Calculation of the pulmonary resistance was not possible because the pulmonary arterial vessels were not entered.

The cineangiograms demonstrated a large aortic root that was displaced far to the left. The aorta arose posteriorly from the left ventricle, arose to the midline, and descended on the right. The pulmonary circuit filled bilaterally via large, persistent, segmental pulmonary arteries that arose from the descending aorta (Fig 1). There were multiple pulmonary branch ste-

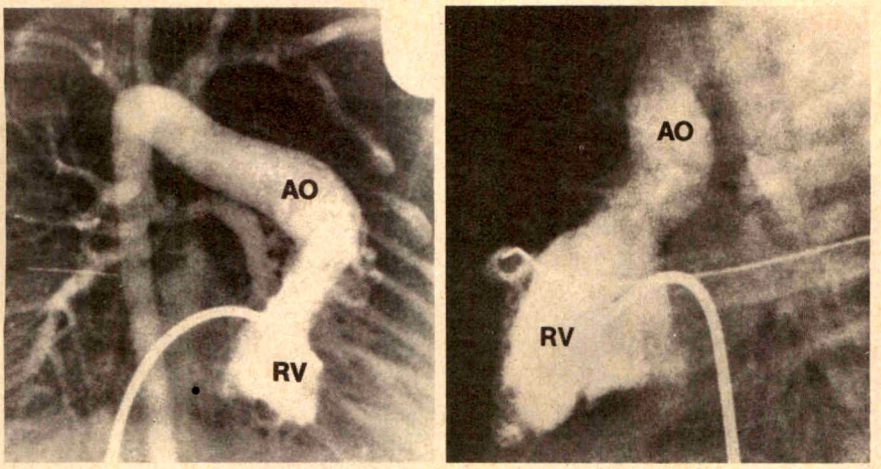

Fig 1.—Right ventriculogram (left, anteroposterior: right, lateral) in infant son showing trabeculated right ventricular (RV) cavity with contrast material streaming across ventricular defect into posteriorly located aorta. Long ascending aorta (AO) was displaced to left and descended on right. Primitive segmental pulmonary arteries arose from descending aorta. Right thoracotomy tube was positioned to relieve preexisting pneumothorax.

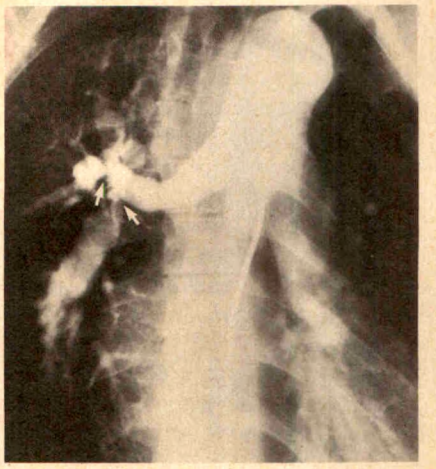

Fig 2.—Descending aortogram in 30-year-old father demonstrating large pulmonary vessels, with multiple-branch stenoses (arrows) on right.

noses. A patent ductus arteriosus was not noted.

The ventriculograms outlined a large interventricular septal defect. The left ventricle was large and posterior; the right ventricle was anterior, to the right, and heavily trabecular. There was absolutely no evidence of a right ventricular outflow tract.

The child was treated medically for his residual pulmonary problems and congestive heart failure. He did well and was discharged from the hospital. At the time of this writing, he was 26 months of age, growing slowly, but otherwise in a satisfactory condition.

CASE 2.—Review of the entire family history, including that of the sibling brother and sister, uncovered no other congenital heart defect except for that of the father. He was a 30-year-old man thought to have a truncus arteriosus type 4, documented by cardiac catheterization in 1961 at the Children's Hospital of Buffalo. He was first noted to have a murmur at the age of 5 months, was mildly cyanotic during childhood, and required neither medications nor surgical intervention. Presently, he reported very few physical restrictions except for fatigue on moderate to heavy exercise. He has been relatively asymptomatic, except for palpitations that began one year ago. In view of his clinical status and due to the recent advances in cardiac surgery, reevaluation and cardiac catheterization were recommended.

The physical examination showed a thin, 30-year-old adult male in no acute distress, but with moderate peripheral cyanosis and clubbing. A blood pressure of 130/40 mm Hg was recorded in both arms. The pulse rate was 96 beats per minute and regular. All pulses were bounding. The point of maximum impulse was palpable in the sixth interspace at the anterior axillary line. There was a prominent apical ventricular lift. No thrills were palpated. A grade 3/6 harsh ejection systolic murmur could be heard over the left sternal edge radiating to the apex. An early diastolic blowing grade 2/6 murmur was auscultated over the same distribution. Continuous murmurs were heard over both lung fields, especially on the right. A loud ejection click was audible at the apex.

Chest roentgenogram showed a large cardiac silhouette with a very prominent aorta descending on the left. The pulmonary artery could not be identified. The pulmonary vascular markings were normal. An arterial blood sample, with the patient breathing room air, demonstrated a Po_2 of 50 mm Hg, a Pco_2 of 39 mm Hg, and a pH of 7.4. The echocardiogram showed a large aorta overriding the ventricular septum. Loss of the septal echoes just below the aortic root suggested a ventricular septal defect. The presence of a normal left atrium in a patient with a truncus arteriosus indicated normal to restricted pulmonary blood flow.

Cardiac catheterization showed that both ventricles were at equal pressures and demonstrated bidirectional shunting. The systemic arterial saturation was 85%. There was no truncal valve obstruction. A 15-mm Hg peak systolic pressure gradient was recorded on pullback from the pulmonary arteries to the descending aorta. The pulmonary resistance of 14.1 units/sq m was 45% of the systemic resistance.

The left ventriculogram outlined a large ventricular septal defect and aortic-mitral continuity. A very large aortic root overrode the ventricular septum. There was no evidence of a patent ductus arteriosus, but very large segmental pulmonary arteries with branch stenoses arose bilaterally from a left descending aorta (Fig 2). No trace of a right ventricular outflow tract or main pulmonary artery could be identified. These findings reclassified the father as having a pulmonary atresia with a ventricular septal defect. Because of the high risk category of this patient and his reluctance to pursue surgery, no further intervention was recommended.

COMMENT

To our knowledge, this report is the first instance of pulmonary atresia with a ventricular septal defect that occurred in a parent and child. Since only a small percent of all patients with this anomaly survive without surgical intervention, little is known of the recurrence risks. The unusually well-balanced hemodynamic state in the case of the father has provided the rare opportunity to document a recurrence in this family.

Similar morphologic patterns have stirred much controversy in the literature over the terminology and classification of this combination of defects. Several classifications have been proposed, including the following: pulmonary atresia with a ventricular septal defect, Fallot's tetralogy with severe right-ventricular outflow hypoplasia, truncus arteriosus type 4, and pseudo-

truncus.[2-6] We have elected to classify these two patients as having pulmonary atresia with a ventricular septal defect, predominantly on the basis of the arterial blood supply to the lungs.[7,8] Both patients had large persistent segmental or primitive pulmonary arteries. They arose from the descending aorta and bifurcated in a pattern identical to pulmonary arteries. Large segmental arteries of this type have been reported in as many as 25% of all patients with pulmonary atresia.[9,10] In addition, a main pulmonary artery could not be demonstrated angiographically. Total absence of the right ventricular outflow tract further qualified both hearts as having pulmonary atresia with a ventricular septal defect rather than Fallot's tetralogy.

Congenital heart defects occur in about eight per 1,000 births each year.[11] Approximately 1% of these are due to single mutant gene, as exemplified by the Holt-Oram syndrome; 4% have gross chromosomal abnormalities, as seen in patients with trisomy; and the remaining 95% are attributed to multifactorial inheritance.[12-14] The multifactorial hypothesis implies interaction between multiple genetic and environmental factors. A complete review of both maternal and paternal families showed no other history of congenital heart defects. All possible etiological factors, including advanced reproductive age in grandparents, maternal exposure to radiation, infection, drugs, high altitude, and other known environmental teratogens, were excluded.

In view of this information, two important questions involving the genetic counseling of this family may be answered. The first is the risk of the parents having further children with congenital heart defects, and the second is the empirical risk of the proband son doing the same. The multifactorial mode of inheritance would suggest at least a 10% risk of recurrence of a congenital heart defect in another child. This risk factor increases with the number of affected first-degree relatives.[15] To illustrate this relationship, if only the father were affected, there would be a 3% to 5% chance of recurrence in his offspring. With the addition of a second case in his son, the risk increased to at least 10%. On the other hand, the recurrence risk to the offspring of the affected son still is of the order of 3% to 5%. Although multifactorial determination is the most likely explanation, the possibility of a rare gene mutation manifested as an autosomal dominant trait cannot be excluded. This would imply a 50% risk of recurrence for any child of an affected person. This possibility emphasized a need for caution in counseling for rare traits.

The survival of this father to reproductive age has provided documentation of a recurring congenital heart defect in his son. Although this is indeed a rare event, the emergence of surgical survivors of previously lethal cardiac defects into child-bearing age makes the question of inheritance even more crucial. These patients will allow a more explicit view into the true incidence, as well as the causes of, these previously fatal and uncorrectable conditions. The clinician must be increasingly aware of the recurrence risks and should focus as deeply on the familial evaluation as he does on the medical and surgical aspects of the defect.

Phosphate Poisoning Complicating Treatment for Iron Ingestion

Mitchell E. Geffner, MD, Lawrence M. Opas, MD

• A 15-month-old child was treated for iron intoxication with a hypertonic sodium phosphate mixture. Clinical deterioration manifested by fever, obtundation, abdominal distention, dehydration, and hypotension followed soon after the administration of this mixture. Such symptoms may occur with either iron overdosage or with phosphate poisoning. At this time, the patient's serum chemistry values included: iron, 49 μg/dL; phosphorus, 24.6 mg/dL; and calcium, 4.5 mg/dL. The hypocalcemia, hyperphosphatemia, and dehydration were treated with parenteral gluconate calcium, intravenous fluids, and general supportive measures. Although the child had an uneventful recovery despite severe phosphate poisoning, therapeutic alternatives, such as sodium bicarbonate, should be used as adjuncts in the treatment of acute iron ingestion.

(*Am J Dis Child* 134:509-510, 1980)

Hypertonic phosphate solutions are recommended in the management of iron ingestion to decrease iron absorption through the production of poorly soluble ferrous phosphate.[1] Despite widespread use, a safe dose for children has not been determined. Hypertonic phosphate therapy may be hazardous if excessive amounts are absorbed, with resultant hyperphosphatemia with hypocalcemia and hyperosmolarity. As signs of hypertonic phosphate toxic reaction such as obtundation, abdominal distention, dehydration, and hypotension are similar to those of iron poisoning, a complication related to this therapy for iron ingestion may go unnoticed, thereby increasing the morbidity of iron overdosage. The present report emphasizes the potential danger of phosphate therapy for a patient with mild iron intoxication.

REPORT OF A CASE

A 15-month-old boy ingested an unknown amount of iron tablets three hours prior to admission. While at home, he vomited twice. Pill particles were noted in the vomitus. Emesis was induced on admission to the hospital, and the vomitus was noted to be free of pill fragments. Initial physical examination showed an alert, active 10-kg child. Temperature was 36.6 °C; pulse rate, 120 beats per minute; respiratory rate, 32/min; and blood pressure, 80/50 mm Hg. The child was well-hydrated, with a soft, nondistended abdomen and a clear sensorium. The patient was thus admitted for observation. At admission, laboratory studies included a serum iron level of 281 μg/dL (normal, 50 to 150 μg/dL) and a hematocrit reading of 38%.

The patient remained asymptomatic until 12 hours postingestion when he passed a bloody stool. Results of his physical examination were unchanged from those at admission. Therapy with intravenous fluids was begun, using 5% dextrose in water with 25 mM/L NaCl and 20 mM/L KCl at a rate of 150/mL/kg/day. In addition, 60 mL of a buffered mixture of sodium biphosphate and sodium phosphate (Fleet Phospho-Soda) were administered orally. The child immediately vomited 30 to 45 mL of clear fluid. In retrospect, it was learned that the solution had been given undiluted at a 66% concentration.

Three hours later, the patient became acutely obtunded, with labored respirations, severe abdominal distention, dehydration, hypotension, and a fever of up to 40.9 °C. On ECG, the QT interval corrected for heart rate (QT_c) was prolonged (0.50 s). Serum laboratory studies disclosed the following values: iron, 49 μg/dL; calcium, 4.5 mg/dL; phosphorus, 24.6 mg/dL; albumin, 4.5 g/dL; sodium, 150 mM/L; potassium, 3.2 mM/L; bicarbonate, 13 mM/L; BUN, 41 mg/dL; and creatinine, 0.8 mg/dL. The hematocrit reading was 35%. A 10% solution of gluconate calcium (1.7 g) was given intravenously during a period of five minutes, and parenteral fluids were changed to 10% dextrose in water with 75 mM/L NaCl and 30 mM/L KCl at a rate of 250 mL/kg/day. The patient showed dramatic clinical improvement within four hours and serum chemical values returned to normal within 18 hours. A total of 5.0 g of gluconate calcium was administered. Recovery was uneventful.

COMMENT

Toxic reactions to hypertonic phosphate solutions have been reported for patients with diminished renal func-

tion,[2-5] gastrointestinal (GI) anomalies,[6-9] and meningomyelocele.[10] Hyperphosphatemia, hypocalcemia, and hyperosmolarity were reported in a 2-year-old child given 1,380 mL of an 11% phosphate solution by gastric lavage for the management of iron poisoning.[11] In addition, normal adults have had hyperphosphatemia within three hours of receiving an oral phosphate mixture in preparation for roentgenographic studies.[12]

Clinical deterioration in the present case was associated with the administration of a highly concentrated phosphate solution. The oral preparation used contains 48 g of sodium biphosphate and 18 g of sodium phosphate per deciliter, a sodium concentration of 4.83 mM/L, and a phosphate concentration of 394 mg/mL (J. D. Stevenson, C. B. Fleet Company, Inc, written communication, Feb 8, 1979). We estimate that our patient retained between 6 and 12 g of the 24 g of phosphate given as well as appreciable amounts of sodium. In the other reported case of hyperphosphatemia complicating iron poisoning,[11] the patient received a total of 84 g of phosphate by continuous lavage; but the amount, if any, of solution retained in the stomach postlavage was not specified. Toxic reaction has been reported in a 5-kg infant who was given only 4.1 g of phosphate.[13] Current recommendations for the management of iron poisoning vary from no mention of phosphate solutions[14] to gastric lavage with a 5% phosphate solution until the return is clear, followed by instillation of 150 mL of the same solution.[15] This instillate alone provides 4.5 g of phosphate, with the potential for exposure to large amounts depending on the volume of lavage. Disregarding errors in dilution as occurred in the present case, current recommendations for phosphate therapy may result in an unwanted toxic reaction. If the use of phosphate solutions is to continue, a safe dose per unit weight must be determined.

Manifestations of hypertonic phosphate poisoning observed in the present case included fever, obtundation, abdominal distention, dehydration, and hypotension. Laboratory studies confirmed hyperphosphatemia, hypocalcemia, hyperosmolar dehydration, acidosis, and hypokalemia. These findings are similar to the toxic reactions described with moderate to severe iron ingestion, and until laboratory results were known, there was considerable confusion regarding the seemingly inexplicable clinical deterioration. The low serum iron level, the temporal relation between clinical deterioration and phosphate administration, and the rapid improvement with calcium and fluid therapy implicate the hypertonic phosphate solution rather than iron poisoning as the cause of these findings.

Symptoms related to hypertonic phosphate poisoning are probably secondary to the high phosphate load with subsequent hypocalcemia as well as to the hypertonicity of the solution. The mechanism by which hyperphosphatemia results in hypocalcemia is unclear, but it may be related to increased extravascular precipitation of calcium.[16] Hypertonic dehydration is secondary to GI water loss and possible absorption of excess sodium. Although hypocalcemia may complicate hypertonic dehydration,[17] serum levels as low as 4.5 mg/dL would not be expected. Renal clearance of phosphate may be impaired by dehydration, but serum levels as high as 24.6 mg/dL would be unlikely to accrue from dehydration alone. Hypokalemia can be seen with either hypertonic dehydration or hypertonic phosphate poisoning.[18]

That reports of complications associated with therapy with a hypertonic phosphate mixture used in the management of iron intoxication are scarce may reflect an unrealized toxic condition. Absorption of phosphate may be enhanced across an intestinal mucosal barrier that is disrupted by the direct irritant action of ingested iron. This factor combined with the lack of an established safe dosage of the phosphate mixture should direct medical personnel treating iron overdosage to use alternative methods of iron-binding, such as 1% sodium bicarbonate. Our case and that of Bachrach et al[11] demonstrate that phosphate should not be used in the management of acute iron ingestion.

Radiological Case of the Month

Lionel W. Young, MD; Contributed by Dennis W. Ross, MD, PhD

A 7-year-old boy with a two-year history of acute lymphoblastic leukemia was hospitalized for evaluation of fever, malaise, cough, rash, and dyspnea. His leukemia was believed to be in remission while he was on maintenance therapy of prednisone and methotrexate.

The present illness started four days prior to admission with fever, malaise, and erythematous rash initially on the face but later extending to the neck and trunk. There was a questionable history of measles one year previously. On physical examination he was an acutely ill dyspneic child with tachycardia, tachypnea, a temperature of 39 °C, and an erythematous maculopapular rash. No Koplik spots were seen. Diffuse rales over both lungs were heard. A chest roentgenogram (Fig 1) was obtained. Arterial blood gas levels were Po_2, 58 mm Hg, Pco_2, 28 mm Hg, and pH, 7.45.

His condition did not improve over 24 hours while receiving antibiotics and O_2 therapy, and an open lung biopsy was performed primarily to exclude *Pneumocystis carinii* infection. A wedge of tissue from the left upper lobe was resected. Microscopic findings are shown in Fig 2 and 3.

Figure 1.

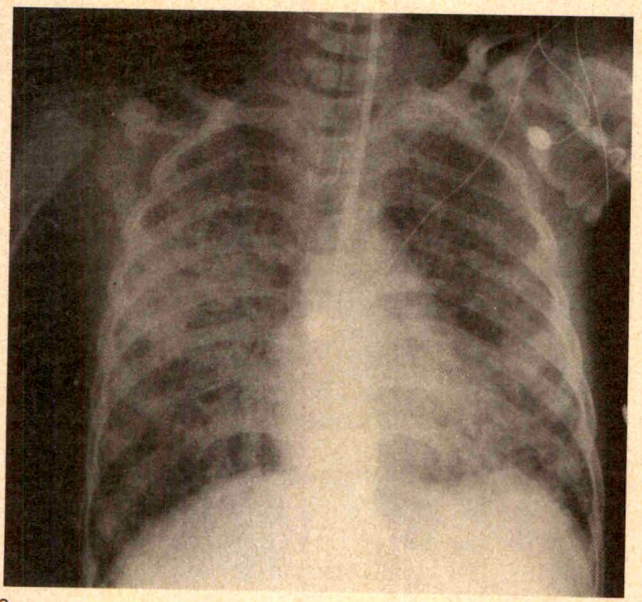

Figure 2.

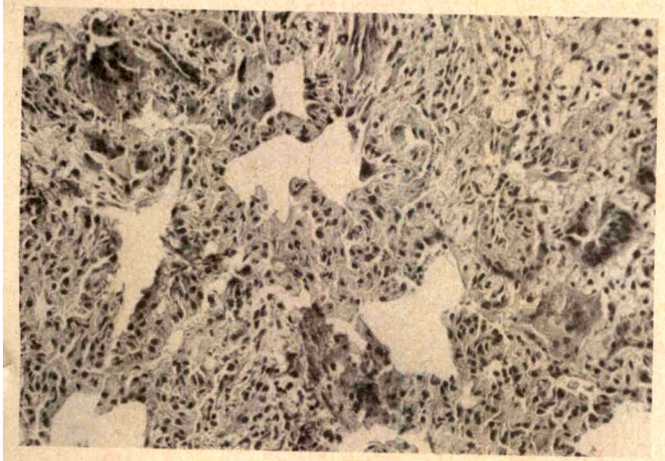

Figure 3.

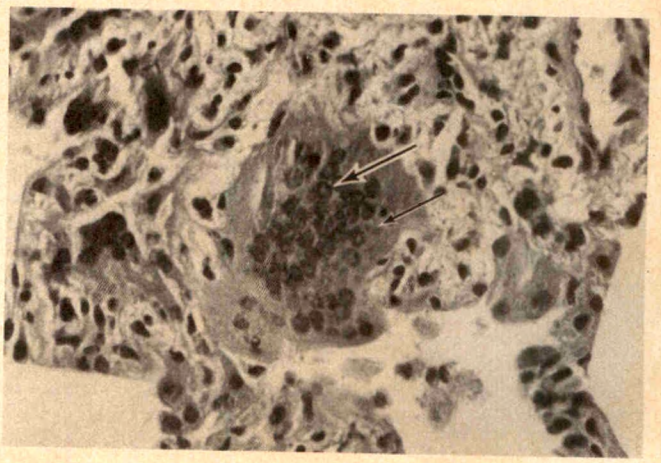

Denouement and Discussion

Fig 1.—Posteroanterior roentgenogram showed diffuse interstitial and alveolar densities in lungs. Heart and mediastinum were normal.

Fig 2.—Biopsy specimen of lung showed diffuse interstitial infiltration characterized by numerous multinucleated giant cells lining alveolar air spaces.

Fig 3.—At high power, giant cells were seen to contain both nuclear (large arrow) and cytoplasmic (small arrow) inclusions.

Giant Cell Pneumonia

The diagnosis of giant cell pneumonia in this patient was made on the basis of the biopsy specimen. In children, pneumonia characterized by an interstitial infiltrate and the presence of multinuclear giant cells with intranuclear and intracytoplasmic inclusion bodies was first described as the entity "giant cell pneumonia" by Hecht.[1] Enders et al[2] and Mitus et al[3] showed this entity to be due to infection with rubeola virus in seven chronically ill patients, five of them with acute leukemia. Two unusual features consistently occurred in their patients: the persistence of viral particles lasting several weeks, and the failure to respond to the infection by the formation of measles complement fixing and neutralizing antibodies. Shah et al[4] recently reported four additional cases of giant cell pneumonia occurring in children with acute lymphoblastic leukemia in remission, three of whom died and one of whom survived. Roentgenographic signs usually preceded respiratory failure. Anderson and Kissane[5] characterize giant cell pneumonia with the constellation of findings: leukemic child, interstitial pneumonia with giant cells, persistence of virus, and no rise in antibody titer as an example of an unusual infection in the compromised host.

Our patient, as in the previously reported cases, showed the following: persistence of virus in the oropharynx as demonstrated by viral cultures; failure to demonstrate an antibody response to infection; and death from progressive anoxia (three weeks after the diagnosis). At autopsy the lungs showed diffuse, noticeable pulmonary fibrosis and no giant cells were observed. Bone marrow examination showed no morphologic evidence of active leukemia.

Review

Vegetarianism in Children

William C. MacLean, Jr, MD, George G. Graham, MD

Vegetarians fall into four main subgroups. The distinction is of practical importance in that the more strictly vegetarianism is adhered to, the more difficult it becomes to assure an adequate diet for infants and children. Lactoovovegetarians exclude meat from the diet although some will eat fish. Milk and eggs are eaten with varying frequency but generally on a regular basis. Lactovegetarians refuse to eat eggs but will drink milk. Pure vegetarians reject any food of animal origin, including milk and eggs. One frequently sees pure vegetarians referred to as vegans. This term is probably better reserved for a subset of vegetarians whose philosophy precludes not only the consumption of foods of animal origin but also the use of any product of animal origin if a substitute exists. The proscription of animal products precludes the use of wool sweaters or leather shoes, for example. In addition to these obvious exclusions, things, such as honey and some cosmetics, whose relation to their animal origins is less obvious are also avoided.

Several points should be made about this classification. Individual vegetarians frequently do not fall conveniently into any one category. Some lactovegetarians or "pure" vegetarians may eat fish. Ovovegetarians who do not drink milk also exist. Second, many people who espouse vegetarianism do so gradually, first removing red meat from the diet, later fish, then milk and eggs. It is not surprising that there is an evolution toward more pure forms of vegetarianism in many cases. Any radical change in diet is difficult to accept and many people ease themselves progressively into more strict vegetarianism in much the same way that casual joggers slowly evolve into marathon runners. Interviews with vegans show a gradual change of philosophy during periods of five to ten years, moving from less strict to more strict vegetarianism and then by logical extension to veganism.[1] Since parents are the prime determinants of their children's diets it is important not simply to identify the vegetarian parent and child but to become aware of the evolution in dietary habits within the family. Since most forms of vegetarianism are compatible with normal growth and good health if certain precautions are taken, updating the history of dietary preferences is particularly important for anticipatory guidance. Finally, people attracted to vegetarianism may also be advocates of other forms of diet therapy, such as megavitamin therapy, natural foods, etc. Some of these practices are potentially harmful in normal children, especially younger infants, and may affect the approach parents will take to traditional medical therapy of illness.

Caring for vegetarian children generally means understandng and communicating with vegetarian parents. Hence, it is useful to look at the reasons people are drawn to vegetarianism. Some religious groups have traditionally been vegetarian. Several of the Indian religions include vegetarianism among the tenets of faith. Although immigrants from India to the United States are relatively small in number, in Great Britain there is a large number of vegetarians of Indian origin. In this country, Seventh-Day Adventists are perhaps the largest traditional religious group following vegetarianism. They are generally lactovegetarians or lactoovovegetarians. Although data are lacking, one might expect fewer nutritional problems from more stable groups in which the precepts of vegetarianism have been passed through successive generations.

The increasing concern for health and nutrition in the past decade has produced the so-called new vegetarians. The presumed health benefits range from decreased incidence of stroke and heart disease to changes in the prevalence of cancer of the colon. In a study of 100 new vegetarians, 35% cited health as a major reason for becoming vegetarians.[2] Day to day health, alertness, and mental functioning were as important as long-term disease prevention. Ethical (25%), metaphysical (14%), and ecological (8%) reasons were also cited. Attitudes on health-related questions were instructive: 55% considered cooking and/or eating a religious or philo-

From the Nutrition and Gastroenterology Unit, Department of Pediatrics (Dr MacLean) and the Division of Human Nutrition, School of Hygiene and Public Health (Drs MacLean and Graham), Johns Hopkins University, Baltimore.

Reprint requests to 615 N Wolfe St, Baltimore, MD 21205 (Dr MacLean).

sophical experience, 31% followed specific dietary teachings, and 66% fasted occasionally but only 26% did so more than once a month. About a quarter of those surveyed took vitamin and mineral supplements regularly. A similar proportion used prescription medication. Finally, 20% mentioned the cost of food as a factor in their decision.

Dwyer and her co-workers,[2] who carried out the study, found substantial differences between those who had a close affiliation with a vegetarian group (termed "joiners") and those not so affiliated ("loners"). Joiners generally had dietary proscriptions that extended beyond vegetarianism per se to questions of organic or natural food and food processing. The patterns of food avoidance varied considerably from group to group. Also noteworthy was the tendency of joiners to attribute symptoms of illness to diet and to seek unorthodox medical care.

A survey of English vegans showed that only 9% approved of routine immunization, whereas 38% sanctioned blood transfusions. This compared with figures of 91% and 97%, respectively, among the population at large.[1] Such studies point up the complexities of dealing with vegetarian parents and the need to inquire about philosophical beliefs as they relate to diet and life-style.

POTENTIAL NUTRITION PROBLEMS

Adequacy of Dietary Protein

Protein quality refers primarily to the amino acid composition of a dietary protein, specifically how closely the concentrations of the essential amino acids come to meeting the requirements of the individual. In practice, dietary proteins are compared with a reference pattern[3] of an ideal protein. When viewed in this fashion, all vegetable proteins have a lower percentage of total nitrogen as essential amino acids and all are relatively deficient in one or more of the essential amino acids. Cereal grains, such as wheat, rice, and corn, all have a low lysine content relative to the other essential amino acids. Legumes, soy protein for example, are low in methionine. These amino acids are termed the first limiting amino acid for the proteins in question.

Complementarity occurs when the first-limiting amino acid of one protein is supplied in sufficient quantities by another protein to offset the deficit. The cereal-legume dietary combinations that have supported traditional societies for centuries are examples of complementarity: cereals tend to be good sources of methionine, legumes good sources of lysine. Eaten in combination the resulting protein quality is higher than that of either individual protein. Thus, although protein quality is of concern in vegetarian diets, especially in those of growing children, whose requirements are higher, this need not be a problem if cereals and legumes are eaten in combination. In some instances, the supplementation of a vegetable protein with its first-limiting amino acid, as is done with the addition of methionine to soy protein isolate-based infant formulas, corrects the essential amino acid deficiency. Similarly, supplementation of wheat with lysine results in dramatic increases in nitrogen retention.[4] In contrast, the addition of lysine to rice is not nearly so effective. This is so because threonine is nearly as limiting as lysine in rice protein, and because the low content of protein in rice and its poor protein digestibility are probably more important in limiting its nutritional value.

Quantity of dietary protein is also a potential problem. This relates as much to questions of digestibility as to the actual protein content of many common staple foods. Healthy infants thrive on human milk, in which approximately 6% of the total energy is derived from protein. When protein requirements are stated in terms of high-quality animal protein, 8% protein calories is generally believed to be a safe level of intake.[5] Legumes provide approximately 20% to 25% of the calories as protein; wheat, 10% to 15%; potato, 6% to 9%; and rice, 7% to 8%. In theory then, cereal-legume-based diets have the potential to provide more than adequate amounts of protein. In practice, the poor relative digestibility of many of the proteins in question, unless the food is highly processed, substantially reduces the amount of nitrogen actually absorbed from these sources.

Legumes have the highest protein content of the vegetables. Mean apparent nitrogen absorption in a group of children consuming a processed bean mixture, however, was only 66%, which is only three quarters that of the apparent absorption from a casein-based diet.[6] In contrast, the digestibility of the soy protein isolate used in infant formulas is excellent.[7]

Wheat provides an interesting example of the effects of processing on digestibility. Whole wheat has a higher protein content and quality than the white flour milled from it. The lower digestibility of whole wheat, however, effectively offsets the increase in protein intake from consuming whole wheat, making white flour an essentially equal source of net dietary protein.[8] Thus, whole wheat products, though endowed with "more nutrition," are often not well tolerated by younger children, whereas products based on milled wheat, such as pasta, are easily digested.[9] Rice protein is less well digested than processed wheat protein and this is not altered to any degree by processing. This is due to the fact that rice protein is present in the grain in small protein bodies that are resistant to digestion and that pass partially undigested in the stool.[10]

The discussion of protein adequacy pertains primarily to pure vegetarians. Rapidly growing infants and children have much higher amino acid requirements than adults. The sheer bulk of some sources of vegetable protein makes it difficult to maintain adequate intakes. Protein adequacy is hardly ever an issue in the lacto-ovovegetarian or lactovegetarian. Brown et al,[11] for example, found in their metabolic study of Bangladeshi children that the addition of as little as 25 mL/kg of milk to a traditional rice-vegetable diet increased protein intakes by 62% and increased apparent nitrogen retention by more than 400%. These results are explained by the fact that total nitrogen content rather than the concentration of any essential amino acid is first limiting in milk protein.[12] This relative excess of essential amino acids in milk results in a disproportionately large improvement in the use of vegetable protein. For this reason, the consumption of several glasses of milk with or without the occasional egg ensures adequate protein nutriture in all vegetarian children.

Adequacy of Energy Intake

Maintenance of adequate energy intake in vegetarian children is difficult for three reasons: the bulkiness (ie, low-energy density, kcal/g) of most staple foods, the poor energy digestibility of some, and the fact that vegetarian diets are generally much lower in fat content. Most adult vegetarians report noticeable weight loss after switching to a vegetarian diet. This weight is usually not regained and as a group vegetarians weigh substantially less than their omnivore peers.[13] To meet only one half of his energy requirements from rice or wheat, a 1-year-old child would have to consume a pound of cooked rice or noodles. Studies in the Orient have shown that small children can consume 20 to 25 g/kg/day of rice at a maximum, quantities that are enormous by Western standards.

Milled wheat products can be tolerated in these amounts but intakes are still larger than we are accustomed to feeding small children. Legumes are no less bulky. Bulkiness may be a problem for adults but it presents the greatest problem for children, whose requirements are higher and whose gastric capacities are less.

Nor is all the energy consumed actually digested. There is a high degree of variability in the energy digestibility of vegetable foods, and this does not always parallel the digestibility of its protein. Although the protein of rice is relatively poorly digested, the starch is very well digested and absorbed, even by infants.[14] The same holds true for milled wheat flour products, such as pasta.[9] In contrast, the carbohydrate in potatoes is less well digested, decreasing substantially the net available energy in the diet and increasing the stool output (G. Lopez de Romaña, MD, G. G. Graham, MD, W. C. MacLean, Jr, MD, unpublished data, December 1979). The same holds true for many legumes. Most of us do not notice these effects of digestibility because the relative contribution of vegetable products to total energy intake of omnivores is much less. In infants who must rely on these foods, however, the effect is often a striking increase in stool weight.

Some of the inadequacy of energy intake can be overcome if fats are eaten in sufficient quantities. Consumption of meat or whole milk automatically carries with it large quantities of fat. Diets devoid of animal protein are low in fat unless exogenous fats are added. In practical terms, this means cooking oils, margarine on rice, noodles or potatoes, or nut butters. As in the case of protein, considerations of the adequacy of energy intake apply to the pure vegetarian, seldom to the lactoovovegetarian or ovovegetarian.

Adequacy of Vitamin Intakes

The major concern in this area is vitamin B_{12}. There is currently no known plant food that contains this vitamin. Vitamin B_{12} is stored in the liver and other tissues. In addition, there is a highly efficient enterohepatic recirculation, resulting in a very small daily turnover. As a result, if initial body stores are adequate, a vegetarian diet can be followed for years by adults without apparent problems. Unless exogenous B_{12} is supplied, however, deficiency is inevitable. This may occur not only in older infants and children but in exclusively breast-fed infants whose mothers are strict vegetarians who shun vitamin supplements.

Vitamin D nutriture is also a potential concern. Fortified milk is one of the main dietary sources for most infants. Egg yolks are also a good source. Although ultraviolet irradiation of 7-dehydrocholesterol on the skin produces cholecalciferol, which is then absorbed and further metabolized to an active form, exposure to sunlight is an unreliable source of the vitamin, especially in north temperate urban areas. In a study in urban and rural Greece, 15% of the infants (nonvegetarians) examined in the winter and spring months had rickets.[15] Nearly all had not received supplementary vitamin D. There was no difference in the prevalence of rickets among those with substantial exposure to sunlight and those with little exposure. Exposure to sunlight cannot be relied on in nontropical areas and since plant foods are poor sources of vitamin D, some source of exogenous vitamin D should be assured.

Both pellagra and beriberi have been related historically to imbalanced and predominantly vegetarian diets. Goldberger showed years ago that the diet common among the poor in the southern United States, namely maize, fatback, and molasses, was pellagragenic. His speculation that a relative deficiency of tryptophan, a niacin precursor, was primarily responsible has since been borne out.[16] Maize has more niacin than human milk but most is bound and not bioavailable unless processed. Tryptophan content is low and total niacin equivalents are about half the amount found in milk. In addition, high leucine intakes from maize may interfere with the conversion of either niacin or tryptophan to nicotinamide adenine dinucleotide, resulting in pellagra.[17] Diets based on maize or sorghum are likely to be pellagragenic, especially in the context of strict vegetarianism.

Dependence on polished rice as the staple food is directly associated with beriberi, making it a potential problem among vegetarians. A high carbohydrate, low-fat diet may increase thiamin requirements.[18] Rice contains adequate amounts of thiamin in the outer layer, most of which is lost in the milling process. The preference of many vegetarians for brown rice should reduce the risk of beriberi. Parboiling is also important in that it reduces the amount of thiamin lost in cooking.

Adequacy of Mineral Intakes

Mineral nutriture has not been recognized as a major problem among vegetarians although some concerns in this area exist. These concerns pertain to the bioavailability of various minerals rather than their actual intakes. Iron is an excellent example. Iron is absorbed from two distinct pools.[19] Heme iron, found in hemoglobin, myoglobin, and ferritin, is animal in origin. Absorption of heme iron is higher than that of nonheme iron and is not affected by other dietary components. In contrast, the absorption of nonheme iron, Fe^{++} and Fe^{+++} inorganic complexes, is highly variable and depends on the foods with which the iron is taken. Two factors known to increase absorption of nonheme iron are the presence of animal protein or ascorbic acid in the diet. Among factors that decrease nonheme iron absorption are phytates and vegetable fiber. The vegetarian often has an intake of iron similar to that of omnivores but none of it is in the more bioavailable form, and the foods consumed diminish the absorption of nonheme iron. Iron nutriture can be a problem even in lactoovovegetarians. Cow milk is a poor source of iron, containing about 1 mg/L. Eggs contain 2 to 2.5 mg/100 g of iron but eggs also tend to inhibit the absorption of nonheme iron.

Bioavailability of calcium, zinc, and copper are negatively affected by diets high in fiber or phytate. It has been calculated that vegetarian diets in some areas of the world contain sufficient phytates to precipitate all the calcium in diet.[20] Oxalates may also form insoluble calcium salts. Both zinc and copper have been mentioned by various authors as potential problems in the vegetarian. As will be seen, these have rarely been a problem in this country.

HEALTH STATUS OF VEGETARIAN CHILDREN

As important as the theoretical nutritional considerations are, the most important question to ask is how well vegetarian children actually fare. Most children in developing countries consume nearly pure vegetarian diets and it is tempting to attribute their poor nutritional status to this fact. This overlooks the heavy burdens of infection to which they are exposed and gives a misleading picture of the nutritional adequacy of the vegetarian diet in a less hostile environment.

Growth

Growth is one of the most sensitive indicators of a child's general health and specifically of his nutritional status. Case reports of poor growth (and other problems) among vegetarians are frequent as they are among omnivores. Few systematic studies of the growth of vegetarian children exist. Shull et al[21] compared the food intake and growth of 72 children younger than 5 years old with established norms. Nearly one half of the children were fed a macrobiotic diet to some degree and one sixth were Seventh-Day Adventists (lactovegetarians). It was difficult in this study to separate completely the data on

zen macrobiotic regimens from those of children consuming more traditional vegetarian diets. Although the lack of well-defined food intake data imposes some limits on the interpretation of the findings, several interesting findings emerged.

When enrolled into the study (mean ages, 30.6 months for girls and 28.7 months for boys), the children weighed less and were shorter than expected from the Harvard reference data. During the studies, gains in weight and length of children younger than 2 years of age were also substandard. The authors speculated that prolonged breast-feeding without appropriate weaning foods might have contributed to this. Growth velocities of children older than 2 years of age approximated the Harvard reference standards. Although at first glance, this appears to be adequate growth these children were already below average for height and weight, so growth should have been above the norm if catch-up were to have occurred. Finally, it was noted that the variability in growth performance was much greater than expected, suggesting that the diet of some children was adequate, that of others quite inadequate.

The only dietary information presented pertained to energy intakes, which were in the range of recommended allowances and did not differ among vegetarian groups. Calculated energy intake and the net available energy after digestion and absorption may differ substantially, however, and the effective energy intake of many of these children may well have been low. In addition, the presence of an unspecified number of lactovegetarians or children fed soy formulas may have improved the apparent growth of the group as a whole, masking more noticeable problems among more strict vegetarians or macrobiotics. Despite these short-comings, this study provides one of the few comprehensive appraisals of growth in vegetarian children and leaves one with the impression that their growth is frequently suboptimal.

Another way to address the question of growth is to follow children whose diets change from pure vegetarian to a less restrictive form. A recent abstract reporting data on an unspecified number of children showed that during a period of approximately two years, height had increased from the fourth to the 41st percentile and weight had increased from the 15th to the 38th percentile when animal protein was added to the diet.[22] Height and weight percentiles attained at the end of the study by these children did not differ from those of siblings who had been lactovegetarians throughout life.

Although the data available are not as complete as one would like, the weight of the evidence is that children with any reasonable amount of animal protein in the diet will more than likely grow normally. A pure vegetarian diet does not seem to preclude optimal growth but the likelihood of this occurring is less. As has been pointed out, however, there may be an association between more strict forms of vegetarianism and a variety of attitudes and life-styles that may adversely affect the growth of the child independent of food intake per se.[2]

Vitamin Deficiency

Most studies of vitamin B_{12} status have been carried out in adults and generally in lactovegetarians. In general, these individuals have been found to have lower serum vitamin B_{12} levels than omnivores although hematological or neurologic evidence of vitamin B_{12} deficiency is lacking.[23,24] A recent abstract comparing complete vegetarians with lactovegetarians and nonvegetarians reported that serum vitamin B_{12} levels were lowest among the strict vegetarians, as would be expected.[25] Several investigators have speculated on the role the colonic flora may play in synthesizing and making vitamin B_{12} available to the strict vegetarian host.

The rapidity with which signs of vitamin B_{12} deficiency can be seen in the rapidly growing infant is illustrated in a recent report.[26] A 6-month-old infant was admitted to the hospital with severe megaloblastic anemia and in coma. Increased pigmentation of the extremities was present. Urinary concentrations of methylmalonic acid and homocystine, both of which require vitamin B_{12} as a cofactor for their metabolism, were increased. This infant had been exclusively breast-fed by a strict vegetarian mother, whose diet had excluded all animal foods and vitamin supplements for eight years. Megaloblastic anemia has also been reported in a breast-fed infant whose mother was a Seventh-Day Adventist.[27] This mother did consume small amounts of animal protein and had taken a multiple vitamin capsule containing vitamin B_{12} during her pregnancy. There seems to be no systematic survey of vegetarian children regarding their vitamin B_{12} status but isolated case reports, such as the aforementioned document, show that the problem is a real one for some infants.

Information concerning vitamin D deficiency and the risk of rickets in these children is somewhat more complete. As part of a survey of the children of new vegetarians, Dwyer et al[28] were able to estimate the vitamin D intake of eight of 17 nearly complete vegetarian children. This averaged 330 ± 229 IU/day (the recommended dietary allowance is 400 IU/day[29]) and was only slightly less than intakes by children consuming less restrictive diets. Nearly two thirds of the children, however, were given supplemental vitamin D on a regular basis. Three of 17 children had intakes of vitamin D of less than 100 IU. Two of eight children for whom data were available had elevated serum alkaline phosphatase values. None of the 17 had clinical signs of rickets.

Mineral Deficiency

Rickets among vegetarians is not confined to young children and is thought in some cases to relate to decreased bioavailability of dietary calcium. Ford et al[30] described eight children of Eastern origin living in England in whom depressed serum calcium concentrations developed between the ages of 9 and 16 years. All eight had been consuming a diet whose staple was chapatis (a traditional Indian flat bread similar to a tortilla) made of whole grain. A seven-week diet trial of a chapati-free diet resulted in an increase of serum calcium levels from 8.4 ± 0.1 to 9.5 ± 0.2 mg/dL. Alkaline phosphatase levels in seven also increased (36 ± 3.5 to 48 ± 6.2 mg/dL). Dent et al[31] have questioned whether binding of calcium by phytates is truly the problem in these children, feeling that adequate vitamin D is more important.

Inadequacy of dietary iron intake has been documented in pure vegetarian children.[32] We are not aware of studies of the prevalence of documented iron deficiency in these children. Similarly, data on zinc and copper are limited. Zinc intakes in adults who are strict vegetarians have not been found to be significantly lower than those of omnivores. Plasma zinc levels appeared to relate to fiber intake rather than to dietary zinc content per se.[33] Severe zinc deficiency with short stature and sexual infantilism has been reported in Iranian and Egyptian children consuming cereal-based diets high in phytates. Concomitant iron deficiency also occurred.[34] To our knowledge, this syndrome has not been seen to date in the United States. Copper deficiency has not been reported in vegetarian children. Since vegetarian diets contain adequate amounts of copper and since copper is so well recycled in the body we would not expect this to be a problem that relates directly to dietary preference.

From the reports of growth, development, and nutritional status, it is clear that while many individual vegetarian children have not fared well, consumption of a strict vegetarian diet does not preclude the possibility of normal growth and development.

An approach to the management of these children to assure optimal growth and development is presented in the next section.

DIETARY MANAGEMENT OF THE VEGETARIAN CHILD

Because dietary restrictions are so variable among vegetarians, it is impossible to produce a set of diet plans suitable for all children. The diet for each child must be worked out using certain general principles. Foremost among these is the recognition that parents who espouse vegetarianism do so in most instances with complete sincerity. Like most parents, they want the best for their children and in this case that means following a set of dietary precepts that they believe facilitate health. The physician must realize that attempts to alter these beliefs radically are unlikely to meet with success. Everyone's time is better spent in assessing the food acceptance and proscriptions of the family and then trying to work out a suitable diet for the child.

Vegetarians are often presumed to have a measure of nutritional sophistication beyond that of the population at large, a presumption that has not been borne out by studies. Consequently, the physician is faced with the problem of educating parents as to the differences in nutrients required to support growth and development in a child as compared with those needed to maintain a fully grown adult. Very likely some alteration of the vegetarian parents' diet willl be necessary to make it suitable for a growing child (omnivore parents similarly make changes). Parents must understand the need for combining cererals with legumes, milk, eggs, or fish if acceptable. A diet that combines several cereals will have variety but will have a severe imbalance of essential amino acids. Even with careful balance, both the parents and the physician should be aware that growth may be slower than expected. Slow growth cannot be equated with poor health and may not be bad per se depending on the degree of retardation. The pediatrician must decide at what point suboptimal growth becomes unacceptable.

From a strictly practical point of view, the physician should try to instill certain dietary practices. Breast-feeding should be the mainstay of the infant's nutrition for at least six months, preferably much longer. Several of the cases cited previously, however, make it clear that careful attention must be paid to the mother's diet in these instances. Among older children, lactovegetarians and lactoovovegetarians will almost certainly do well and the only real concern with these children is the assurance that adequate amounts of milk and eggs are eaten and that the family does not evolve to a more restrictive form of vegetarianism without the physician's knowledge. The lactoovovegetarian needs positive reinforcement, in particular, pointing out the value of dairy products to the child's nutritional well-being.

The critical importance of the cereal-legume paradigm for older children has been previously stressed. In addition, the strict vegetarian child should be changed into a de facto lactovegetarian through the use of soy formulas whenever possible. Formulas made of soy protein isolate with added methionine are nutritionally adequate for the infant who is not breast-fed and for the older child who has been weaned. Soy formulas are usually acceptable to pure vegetarians although some will eschew their use because of the high degree of processing involved in their manufacture. In addition to assuring reasonable protein and energy intakes, commercial soy formulas provide proportional amounts of vitamins and major and trace minerals. In discussing the use of soy formulas with parents, these proprietary formulas should not be confused with homemade soy milks used by some sects. The latter may be no more than the white liquid produced when ground soy beans are soaked and filtered.

A second practical goal for the physician is to gain acceptance by the parents for the use of supplemental vitamins and iron. A sizable part of the requirement of most minerals and vitamins can be supplied by a soy formula but as the child grows older and receives a smaller proportion his total energy intake from formula an additional source of vitamins D and B_{12} and iron must be assured.

Variety in the diet should be stressed. This is especially important from the point of view of complementarity of vegetable proteins. It also relieves monotony and probably helps to maintain adequate food intakes.

Certain foods are not considered safe for infants, however, and are potentially greater problems in some vegetarians. Vegetarians often prefer "natural" foods and may substitute honey for table sugar. The recent reports of botulism in infants fed honey containing botulinus spores but not preformed toxin make this an inappropriate infant food.[35] The tendency to do home canning of fruits and vegetables makes botulism a greater potential concern among vegetarians. Vegetables juices, in particular spinach and carrot, may be inappropriate because of their potentially high contents of nitrites.[36] Many vegetarians consume large quantities of nuts as sources of calcium, iron, and copper. Although nut butters are excellent foods for children, the dangers of aspiration make whole nuts unacceptable. Commercially produced peanut flours contaminated with aflatoxin, a metabolite of *Aspergillus flavus*, have been associated with childhood cirrhosis in India.[37] Crude peanut oils and parboiled rice have also been found to contain the toxin. Aflatoxin has also been linked epidemiologically to Reyes' syndome in Thailand.[38] We are not aware of similar reports in this country.

A final consideration in the care of these children is to try to maintain them in the traditional health care system. Nutritional status is a function of both food intake and infectious or chronic diseases that affect food use. Vegetarian children have a smaller margin of safety in their food intake. Preventive aspects of pediatrics, such as immunization, take on additional importance for them. Because vegetarians as a group tend to shun orthodox medical care, their children are potentially exposed to a variety of untraditional approaches to the treatment of disease, many of which may be harmful. Anything that can be done to minimize this aspect is desirable.

ZEN MACROBIOTICS

Macrobiotic diets are discussed separately for several reasons: it is the philosophy that seems to be espoused by the largest group of new vegetarians. A macrobiotic diet is far more restrictive than pure vegetarianism when the most "desirable" dietary regimen is followed. The most severe cases of malnutrition among infants following unconventional dietary practices seem to have been associated with Zen macrobiotics.

The Zen macrobiotics philosophy is based on the beliefs that Zen Buddhist monks have followed this approach to diet and that they are among the healthiest people in the world. It is difficult to substantiate either of these claims. Zen macrobiotics were introduced into this country by George Ohsawa.[39] There are ten dietary regimens, numbered from −3 to +7. In the progression from lower to higher, desserts, fruits and, later, animal foods are removed from the diet and the percentage of energy from cereals is increased from 10% at level −3 to 100% at level +7. "Cereals" in this case means an exclusive or heavy concentration on brown rice in the diet. Liquid is taken only sparingly.

All foods are given a rating in terms of yin and yang. Brown rice has a value 5 yin to 1 yang (based on the K:Na ratio). Other foods must be eaten in combination, according to their yin or yang value, to maintain the overall dietary ratio at 5:1. Dietary regimens with plus numbers on the scale are generally considered safe. Diets with minus numbers can be indulged in occasionally but are not believed to offer a margin of safety. When beginning the macrobiotic regimen, the adherent is urged to start at level +7 (100% cereal) for several weeks and then add other foods as necessary. In times of illness, a return to the 100% cereal diet is urged. In addition, "industrialized" food and all foods not naturally grown are avoided. Other teachings include the following: body odor comes from animal food; mixed diets create mixed thought processes. In contrast, children require less salt and more water.[40]

The potential nutritional problems for both adults and children increase as one ascends the order of dietary regimens. The lowest five regimens all include foods of animal origin. Game, poultry, and eggs are preferred. Adequate diets for children might be possible at these levels, although 50% of dietary energy is derived from cereals at level 2. At higher levels, the diet becomes more prohibitive than strict vegetarianism and the high percentage of calories derived from cereals combined with the bulk of the diet make it difficult at best to feed children properly. The increasing dependence on rice as a protein source is also dangerous. Supplements of vitamins are shunned. Soy-based formulas are generally unacceptable because they have been processed. A homemade soy-water is used but this is of doubtful nutritional value.

The literature confirms the theoretical disadvantages of macrobiotic diets for children. In the growth study of Shull et al,[21] the growth velocities of these children tended to be less than those of nonmacrobiotic vegetarians. The difference was statistically significant for rates of weight gain between ages 2 and 5 years. In the study by Dwyer et al,[28] calculated intakes of vitamin D by macrobiotic children were 33 ± 67 IU/day compared with 372 ± 267 IU/day by more traditional vegetarians. Physical findings suggestive of rickets were noted only among macrobiotics. Four cases of florid rickets were reported, all in children following macrobiotic regimens.

Nutritional disorders have not been confined to suboptimal growth and rickets. Marasmus and kwashiorkor have been reported by a number of authors, as have scurvy and anemia. A recent report from England emphasizes the inappropriateness of the diet to which macrobiotic infants can be exposed.[41] One infant had been breastfed for four weeks and was then weaned to an "infant food" known as kokoh, a mixture of rice, wheat, oats, beans, and sesame flour. He was admitted to the hospital at 9 weeks of age with poor weight gain, edema, hypothermia, and hyponatremia (serum Na concentration, 114 mEq/L). A second infant had been weaned at 5 months to a diet of kokoh, vegetables, and brown rice. She was admitted to the hospital at 12 months of age with marasmus and rickets. Four malnourished infants of macrobiotic Black Hebrews living in Israel were also recently reported.[42] All had marasmus or kwashiorkor, vitamin B_{12} deficiency, and rickets on admission to the hospital; one died. The authors of both reports were able to negotiate a more acceptable diet for the infants after discharge although a court order was used as a lever in several of the British cases.

All of the potential nutritional problems of pure vegetarianism are concerns for children raised in Zen macrobiotic families, only doubly so. In contrast to vegetarianism, there seems to be no way that a child can remain healthy if a higher level Zen macrobiotic regimen is followed. Furthermore, the parents are likely to be the most zealous of those following unconventional diets. One should try to convince the parents that they should move their child to a lower-order dietary regimen that deemphasizes cereals and allows meat or dairy products. An attempt to supplement the diet with vitamins, especially B_{12}, should be made but the reported experience suggests that this will not meet with great success.

HEALTH FOODS

A brief word about health foods is in order although consumption of health foods is not confined to vegetarians. Many vegetarians, especially Zen macrobiotics, use health foods. The exact definition of health foods is variable but the term usually refers to natural foods, ie, unprocessed foods and so-called organically grown foods.

Food processing has unjustly acquired a bad reputation. As has been mentioned previously, milling or amino acid supplementation may vastly improve the digestibility or quality of vegetable protein. Legumes in particular contain a variety of toxicants and these require processing before they are suitable for consumption. The soaking of beans overnight is an example of one type of traditional processing of legumes. Cooking itself is a form of food processing that vastly improves the digestibility of many foods. With the possible exception of some legumes, the inclusion of unprocessed foods, such as whole grain cereals in the diet, is of no real concern to the older nonvegetarian child who is consuming a normal diet. The decreased digestibility of some natural foods is more than offset by the nutrients available in the rest of the diet. The situation in which natural foods cause concern is in the child who depends on staples for the majority of energy and protein in the diet. The inferiority of digestibility may prove important.

The natural food concept also extends to milk. Some natural food advocates prefer raw unpasteurized milk. Not all raw milk is certified and even when it is there is not absolute assurance that it is free of pathogenic organisms. Control of the quality of raw milk is difficult since it does not pass through centralized dairy processing plants.[43]

Natural vitamin supplements are an important aspect of the natural food movement. Central here is the belief that the naturally occurring form of a vitamin is used better by the body than the synthetic form. The "natu-

ral" nature of most of these products, however, does not stand up to close scrutiny. A favorite is rose hips, with an ascorbic acid content of approximately 2%. The ascorbic acid content is adjusted to about 50% with synthetic ascorbic acid prior to marketing. To do otherwise would require a tablet the size of a golf ball.[44] Similarly, natural B vitamins are yeasts or other food bases highly supplemented with synthetic forms of these vitamins.[44]

Vegetables raised without inorganic fertilizers or pesticides (organic foods), offer no nutritional advantage or disadvantage.[43] It should be pointed out that there are no standards regulating the use of the word organic. There is no guarantee that organic foods are in fact grown in any way differently than most fruits and vegetables. The main drawback to organic foods is their cost. A market basket of 33 foods purchased for $17.49 in a supermarket in 1976 cost 35% to 60% more when bought in health food stores.

CONCLUSIONS

A wide variety of dietary patterns are encompassed by the term vegetarianism. The lactovegetarian or lactoovovegetarian is not a vegetarian in the strictest sense and the diets of these children in many instances will differ little from the usual diet in the United States, with its emphasis on milk consumption. Growth and development can be expected to be normal. Adequate growth in pure vegetarian children is more difficult to achieve. Heavy reliance on soy formula and adequate supplementary iron and vitamins are the nutritional approaches most likely to succeed. In its most strict forms, the Zen macrobiotic diet is inadequate for infants, children, and adults. If the parents are unwilling to retreat to a less restrictive macrobiotic regimen, legal assistance may well have to be sought in the child's behalf.

This study was supported by research grant AM HD-10111 from the National Institutes of Health, US Public Health Service, and by research contract AID/ta-C-1286 with the Agency for International Development, US Department of State.

Nosocomial Pertussis: Possible Spread by a Hospital Visitor

Recently, studies of the epidemiology of pertussis have suggested that young adults with waning immunity and mild illness constitute a major reservoir of infection.[1] Such patients are more commonly the source of exposure to pertussis in children than previously thought. We report an outbreak of nosocomial pertussis involving ten hospital personnel and patients that was traced to the mother of a patient with pertussis. This outbreak underscores the problem of pertussis in young adults and their potential role in the nosocomial spread of this infection.

See also p 521.

The Outbreak.—The organism was introduced into the hospital by a 4-week-old child (patient 1) and her mother, aged 16 years. The mother reported that she had rhinitis and cough eight days after the birth of her child. The child became ill with similar symptoms at about 3 weeks of age, was admitted to an area hospital on Sept 1, 1978, and was transferred to our hospital on Sept 3, 1978.

On admission to the pediatric intensive care unit (PICU), the child was given erythromycin ethylsuccinate and placed in respiratory isolation for the suspected diagnosis of pertussis. Nasal smears for fluorescent antibody (FA) to pertussis were taken from both patient 1 and her mother at the time of admission and were sent by mail to the state health department laboratory. The patient's FA smear was reported as positive within 72 hours; her mother's slides were broken in the mail and the smear was repeated. Although the repeated FA smear was subsequently positive, this was not reported to the house staff immediately, and the mother was not treated with antibiotics until her daughter's discharge from the hospital. During the child's hospitalization, the mother had frequent contact with nursing staff and other patients and visitors in the PICU.

On Sept 20, 1978, the FA smear from a 4-week-old patient in the PICU, taken as part of an evaluation for fever and respiratory distress, was reported as positive. At this time, the infection control program conducted an investigation.

Materials and Methods.—An attempt was made to trace the movements of patients and personnel within the PICU from Sept 3 to 20, 1978. Personnel were interviewed for histories of respiratory illness and to determine the extent of contact with both the patient and her mother during this time. The mother was also questioned regarding her contact with other patients and personnel in the PICU. Nasal smears for pertussis FA and sera for agglutination titers to pertussis were taken from patients, nursing personnel, and pediatric house staff who were present in the PICU from Sept 3 to 20, 1978.

A case of pertussis was defined as the presence of symptoms of rhinitis or cough or nasal congestion and the following: (1) a positive pertussis FA nasal smear; and (2) acute and convalescent sera showing a fourfold increase in pertussis microagglutination titer and absence of a fourfold increase in complement fixation titer to adenovirus, all occurring in a patient or personnel (or a contact of personnel) who had been present in the PICU during this time. Cultures for pertussis were not done.

Results.—In addition to patient 1 and her mother, eight additional cases of pertussis were detected. Six cases in adults were diagnosed: four nurses, the husband of one nurse, and one pediatric house officer. The adults ranged in age from 22 to 36 years (mean age, 23.4 years), and all gave histories of complete immunizations in childhood. The two patients involved were 7 and 16 weeks of age.

When interviewed, the mother reported having had frequent contact with both patients in the beds adjacent to her daughter's. This included holding the children and often assisting in tasks such as feeding them. She also had frequent contact with two of the nurses who subsequently became infected. She remained symptomatic during this time, with nasal congestion and rhinitis, and was not treated with erythromycin until after her daughter was discharged from the hospital on the 22nd hospital day.

Comment.—Natural infection with pertussis is thought to confer long-lasting immunity.[2,3] However, Lambert has reported that protection against pertussis decreases as the interval between vaccination and subsequent reexposure increases.[4] In a community outbreak, an attack rate of 95% was seen in persons who had been vaccinated 12 years or more prior to their exposure to pertussis. In this same study, six of 12 subjects aged 20 years or older who had been completely immunized in childhood contracted pertussis.

In a review of 400 cases of pertussis occurring during the past 18 years, Nelson noted several changes in the epidemiology of this disease.[1] In the six-year period from 1971 to 1977, the incidence of pertussis in children decreased by more than 50%, whereas the number of cases occurring in children less than 12 weeks of age doubled, to 30% of the total. During this period, the most common source of acquisition of pertussis was an adult household contact rather than other children in the household, as in previous years. The present outbreak emphasizes the importance of young adults as a reservoir of pertussis. Indeed, it seems that patient 1 was exposed to pertussis during the first 2 weeks of life, and that her mother was the source of infection.

We believe that this child was not responsible for secondary spread within the hospital since she continued to receive respiratory precautions during the early phase of her illness. In addition, since antibiotics quickly eradicate the organism from the res-

piratory tract without affecting the course of the disease,[5] it would seem likely that the patient's teenaged mother was responsible for infecting not only her daughter but two other patients (patients 2 and 3) and two of the nurses.

Based on other histories obtained from personnel, it seems that one nurse infected her husband and that patients 2 and/or 3 infected the two remaining nurses who "floated" through the unit for only short periods of time. Since the intern who was infected did not provide care for the index patient or have contact with her mother, he was probably infected by a nurse with whom he had worked during his rotation in that unit.

The loss of protection against pertussis and its potential to infect adults has been well demonstrated in two previous nosocomial outbreaks where pediatric patients have been responsible for infection in adult hospital personnel.[6,7] This most recent nosocomial outbreak serves as a reminder that not only does pertussis affect adults but these adults, particularly family members and hospital personnel, may be responsible for nosocomial spread of this disease. The fact that this teenaged mother was initially overlooked as the source of her daughter's infection was probably responsible for spread of pertussis to hospital staff and patients.

Adult household contacts of children with pertussis should be questioned for a history of a recent respiratory illness and should be considered for antibiotic treatment until infection can be ruled out. Moreover, visitors or hospital personnel with any acute respiratory illness should be excluded from patient areas whenever possible. This infection control practice should theoretically minimize transmission of pertussis as well as other respiratory pathogens (eg, influenza, respiratory syncytial virus) to hospital patients and personnel. Such a practice is particularly important on pediatric units where susceptible children often congregate in playrooms and other common areas.

Nosocomial Pertussis: A Failure of Erythromycin Treatment and Prophylaxis

A variety of antimicrobial agents have been used to treat children with pertussis to decrease the excretion of *Bordetella pertussis* and we hope prevent transmission of the infection to other children.[1-5] Erythromycin is considered the drug of choice for *B pertussis* infections by the American

See also p 520.

Academy of Pediatrics Committee on Infectious Disease because of its low toxicity and superior efficacy in eradicating this organism from the nasopharynx when compared with other antimicrobial agents.[3-7]

We report the failure of seven days of erythromycin therapy to eradicate *B pertussis* from the pharynx of an infant. A second infant who was exposed to this child also contracted pertussis in spite of prophylactic use of erythromycin.

Bacteriologic Methods.—Nasal washing specimens were cultured and examined by direct fluorescent antibody (FA) techniques. Fresh control slides were prepared for each FA examination using stock *B pertussis* and *B parapertussis* cultures. Suggestive colonies of Gram-negative rods growing on modified Bordet-Gengou media were identified as *B pertussis* if fluorescence was 3+ or 4+, control slides stained appropriately, and the organisms failed to grow on chocolate agar.

Report of Cases.—CASE 1.—This 9-week-old, unimmunized female infant was admitted to the hospital after three weeks of rhinorrhea and two episodes of cyanosis and limpness after paroxysmal coughing. During nasal suctioning, she had a respiratory arrest requiring resuscitation with bag and mask.

Her admission WBC count was 21,700/cu mm, with 13% segmented neutrophils, 78% lymphocytes, 5% monocytes, and 4% eosinophils. A nasal washing was negative by direct FA techniques for *B pertussis* but positive by culture.

She was treated with intravenous fluids, humidified oxygen, pertussis immune globulin (human) at 1.25 cc/day intramuscularly for five days, and erythromycin ethylsuccinate at 55 mg/kg/day for seven days. Because of severe life-threatening paroxysms, she was also given hydrocortisone sodium succinate at 30 mg/kg/day intravenously for three days, followed by tapering doses for the next six days. The severity and frequency of paroxysms diminished from 14 per day on day 1 to none on day 9. After seven days of erythromycin therapy, she was taken out of isolation and placed in a seven-bed ward for three days prior to discharge. One day after erythromycin therapy was discontinued, a nasal washing was negative by FA testing. However, the culture from this specimen subsequently had *B pertussis* growth.

She was readmitted five days later because of a mild recurrence of paroxysmal coughing that gradually resolved during the next 14 days. Viral cultures and a repeated nasal washing for *B pertussis* were negative during this admission.

Immediate family contacts were negative by FA techniques and culture for *B pertussis* at the time of the first hospital admission, and all members received five days of erythromycin prophylaxis prior to her relapse.

CASE 2.—This 5-month-old male infant was kept in an open crib 1.83 m away from case 1 for three days after the discontinuation of isolation procedures. He had received only one diphtheria and tetanus toxoids and pertussis vaccine immunization because of a chronic neurological disorder. A nasal washing was negative for *B pertussis* five days after the initial exposure to case 1. He was started on a regimen of erythromycin ethylsuccinate at 55 mg/kg/day at this time, but three days into therapy, he had coryza and a mild cough. The WBC count was 13,600/cu mm, with 27% segmented neutrophils, 29% band forms, 27% lymphocytes, 12% monocytes, and 5% eosinophils. A nasal washing was positive for *B pertussis* on culture.

The coughing became paroxysmal during the next four days, but no cyanosis or complications were noted. This child received an additional eight days of erythromycin therapy prior to discharge, and all symptoms gradually resolved during a two-week period. A repeated nasal washing obtained at the time of discharge was negative for *B pertussis* by both FA techniques and culture.

Results.—Five of the nine infants who shared a room with case 1 had nasal washings obtained five days

after the earliest possible exposure. All five, including case 2, had negative FA and culture results at that time.

Seven infants received erythromycin ethylsuccinate at 40 to 50 mg/kg/day for five days. One infant was receiving chloramphenicol palmitate for *Haemophilus influenzae* meningitis, and one infant did not receive any prophylactic antibiotics. All of the exposed infants were less than 20 months of age, and three infants had not received any immunizations at the time of exposure. The private physicians or parents of all exposed infants were contacted by telephone three weeks after the initial exposure. Only case 2 had respiratory symptoms.

Comment.—The Public Health Service recommends isolation of patients with pertussis "for seven days after the onset of therapy with either erythromycin or ampicillin."[8] However, seven days of erythromycin therapy failed to eradicate *B pertussis* from case 1 and discontinuing isolation led to the transmission of disease to case 2.

Although the number of children studied is small, data from the first patient described here and from other studies suggest that seven days of erythromycin therapy may be inadequate to eradicate *B pertussis* from the nasopharynx. Bass et al have shown that erythromycin was more effective than tetracycline and chloramphenicol in eradicating *B pertussis* from the nasopharynx and that almost all patients had negative cultures after five days of therapy.[4] However, bacteriologic relapses were observed in three of 20 patients treated with tetracycline or chloramphenicol for seven to ten days, and a transient relapse occurred in one of two children treated with erythromycin for ten days. No relapses were observed in patients treated with erythromycin for 14 days by Bass et al or Linnemann et al.[9]

The strain of *B pertussis* isolated from our patients could have been resistant or relatively resistant to erythromycin. Unfortunately, the organism did not survive repeated subculturing, and antibiotic sensitivity testing could not be performed.

It is conceivable that patient 2 could have been infected by someone other than case 1. However, there were no other known cases of pertussis in the hospital, the family members of case 1 were culture-negative, and they also had received erythromycin.

Although several reports have suggested that treatment of individuals exposed to *B pertussis* with erythromycin might prevent infections, we are unaware of any controlled studies.[4,9,10] Case 2 did not receive erythromycin until five days after the earliest exposure to case 1. This delay could have been responsible for the failure of prophylaxis. Since most patients with pertussis are highly infectious for one or more weeks before the diagnosis is made, similar delays in the administration of chemoprophylaxis are likely in other settings. These uncertainties regarding the timing and efficacy of erythromycin chemoprophylaxis only emphasize the point made by Linnemann et al more than five years ago.[11] A large-scale, controlled trial of erythromycin chemoprophylaxis for pertussis is still needed.

Adherence of *Staphylococcus aureus* to Infant Nasal Mucosal Cells

Bacterial colonization in the oral cavity of humans is at a low level during the first day after birth and increases to the adult level on the third day.[1,2] The reason for this lack of bacteria during early neonatal life has not been explained. The adherence capacity of groups A and B streptococci to buccal mucosal cells at birth (day 1) is minimal, but it rapidly increases to the adult level on day 3. *Staphylococcus aureus* varies in its ability to attach to nasal epithelial cells.[3] Nasal *S aureus* carriers have greater affinity for *S aureus* than do noncarriers. The epithelial cells of the newborn may serve as a useful tool in further studies of the mechanisms involved in bacterial binding and colonization on mucosal surfaces in man. This colonization is usually requisite for subsequent clinical infection.

The present study investigates the adherence of *S aureus* to nasal mucosal cells in newborns and compares this with the binding capacity of the adult nasal epithelial cells. We chose nasal epithelial cells because the nose is an important reservoir for *S aureus*.

Subjects and Methods.—Healthy infants were selected. Informed consent was obtained from parents after the nature of the procedure or procedures had been fully explained. Nasal epithelial cells were obtained on days 1, 2, 3, 4, and 5 after birth. Corresponding samples were collected from adults for comparisons. Nasal epithelial cells were collected from infants and adults by gently scraping epithelia from the anterior nares with a sterile, wooden applicator by methods previously described.[3]

Staphylococcus aureus was grown in trypticase soy broth, washed three times in phosphate buffer, and resuspended at about 10^8 organisms per milliliter of broth for the adherence experiment. One milliliter each of mucosal cell preparation and bacterial suspension were mixed and incubated at 35 °C for 90 minutes. After incubation, the cells were washed free of unattached bacteria on an 8-μ filter using 40 mL of 0.075M sodium phosphate buffer. Direct smears were prepared from each epithelial cell suspension and stained for 15 s with Gram's crystal violet. The numbers of bacteria adhering to epithelial cells were counted under the light microscope. Control epithelial cell suspensions were incubated with phosphate buffer (without bacteria) to determine the number of bacteria already adhering to the cells.

Results.—Attachment of *S aureus*

Binding of *Staphylococcus aureus* by Nasal Epithelial Cells From Newborns of Various Ages*

Day of Life	Age, hr	N	% of Adherence†	P
1	24 ± 3	10	22.0 ± 10.7	< .001
2	48 ± 4	10	25.0 ± 11.8	< .001
3	74 ± 4	10	38.0 ± 6.8	< .001
4	96 ± 3	5	35.0 ± 7.5	< .001
5	120 ± 4	5	98.0 ± 27.0	> .873

*Fifty epithelial cells were counted for each age group.

†Adherence of *S aureus* to adult nasal mucosal cells was considered 100%. The average ratio of bacteria to epithelial cells was less than 20 during the first four days of life and increased to adult level (40 to 70 bacteria per epithelial cell) on day 5 (120 hr).

to the nasal mucosal cells of infants and adults was compared (Table). The binding of *S aureus* by nasal epithelial cells was markedly less on day 1 ($P < .001$) and remained at a decreased level until day 4 ($P < .001$). On day 5, the *S aureus* binding to epithelial cells reached the adult level. There was no significant difference in adherence of nasal mucosal cells in the adult and the 5-day-old infant ($P > .873$).

Comment.—We have demonstrated that the ability of nasal epithelial cells to bind to *S aureus* is considerably decreased during the first four days of life and reaches adult levels on the fifth day. Ofek et al[1] showed that the binding of buccal epithelial cells to streptococci groups A and B was minimal on days 1 and 2 and reached the maximal level on day 3. The failure of bacteria to adhere to the mucous membrane of newborns may be due to the immature receptor sites or to other local factors in the host because streptococci binding appears to be due to the lipoteichoic acid located on the surface of the organisms.[1,2] Teichoic acid, a component of the *S aureus* cell wall, mediates the binding of these organisms to nasal mucosal cells.[4] Knowledge about the receptor sites for staphylococcal binding on infant epithelial cells is lacking. Nasal colonization of the infant with *S aureus* usually follows staphylococcal colonization of other body sites.[5,6] To our knowledge, the temporal sequence of staphylococcal binding at these other sites has not been investigated to date. It would be of interest to know whether in vitro attachment of the cells from these sites binds *S aureus* earlier than do nasal mucosal cells.

A better understanding of the mechanisms involved in the attachment of *S aureus* to infant nasal epithelial cells should provide useful information regarding colonization of the mucous membranes of newborns. This colonization which is usually requisite for clinical infection of intact skin, occurs in from one third to one half of hospital-delivered infants. The data presented here relate to in vitro introduction of staphylococci to nasal mucosal cells. Extensive study will be required to correlate the extent and ease of staphylococcal adherence to mucosal cells and the frequency of clinical infections.

Corpus Luteum Hemorrhagicum: An Unusual Complication of Anticoagulant Therapy

Hemorrhagic complications of oral anticoagulant therapy are well known. The purpose of this communication is to report an unusual and potentially life-threatening complication of long-term anticoagulant therapy that, as far as we know, has not been previously reported in the pediatric literature.

Report of a Case.—A 17-year-old girl was admitted to the hospital because of a rapidly decreasing hematocrit reading and abdominal pain. She was known to have rheumatic heart disease since age 7 years, and at 13 years of age, her mitral valve was replaced with a Björk-Shiley artificial valve. Postoperatively, she was given daily penicillin G potassium and warfarin sodium. Two months prior to admission, the patient had a transient episode of cerebral ischemia after poor compliance with her warfarin regimen. Her warfarin dose was increased, and she subsequently did well, with prothrombin times that were 2½ times control values. One month prior to admission, she had been hospitalized briefly at another hospital for evaluation of abdominal pain and hematuria that resolved without specific therapy. Prothrombin time was not available.

Four days prior to admission, a prothrombin time was three times the control value, and she was told to temporarily discontinue warfarin therapy. Two days later, she was admitted to another hospital with abdominal pain and vomiting. Hematocrit reading was 32%. Her abdominal pain continued, and her hematocrit decreased to 15%, with no evidence of external blood loss. She was transferred to Children's Hospital of Pittsburgh after receiving a 600-mL transfusion of packed RBCs.

Menarche was at 13 years of age, and regular periods had occurred every four to five weeks without menorrhagia. Her last menstrual period was 2½ weeks prior to admission. She denied sexual intercourse.

On examination, the patient was an obese girl in moderate distress from abdominal pain. The pulse was 116 beats per minute; blood pressure, 120/60 mm Hg without orthostatic change; respirations, 22/min; and temperature, 37.9 °C. The chest was clear. Examination of the heart disclosed the loud opening and closing sounds of the Björk-Shiley artificial valve. A grade 2/6 systolic ejection murmur was heard best at the left sternal border. Diastole was clear. There was diffuse guarding and rebound tenderness in both lower quadrants of the abdomen, without point tenderness, organomegaly, or palpable masses. Pelvic examination showed a normal vaginal introitus, with a normal midposition uterus. No adnexal masses were felt on bimanual examination although there was a fullness in the cul-de-sac on rectovaginal examination. Stool guaiac test was negative. Neurologic examination was normal.

The hemoglobin level was 6.9 g/dL; hematocrit reading was 20%; WBC count was 14,000/cu mm, with 85% segmented forms, 4% lymphocytes, 7% monocytes, and 4% band forms. Radioreceptor assay for human chorionic gonadotropin was negative. Prothrombin time was 20 s, with a control of 11.5 s; partial thromboplastin time was 62 s, with a control of 32 s. Serum electrolytes and BUN levels were normal.

Chest roentgenogram was normal except for the prosthetic valve. Abdominal roentgenogram showed intraperitoneal fluid with calcific densities in the lower abdomen, which were "tooth shaped."

Clinically, intraperitoneal hemorrhage was suspected. The patient's prolonged prothrombin time was corrected by administration of fresh frozen plasma and vitamin K. Her hematocrit reading rapidly stabilized after transfusion with packed RBCs. Within 24 hours, the signs of peritoneal irritation resolved.

An abdominal sonogram showed a large cyst of the left ovary, containing calcium. The patient was given 5,000 units of heparin sodium subcutaneously every 12 hours, and 5 days after admission, she underwent elective surgery. The abdomen contained approximately 600 mL of old blood. A left ovarian cystectomy was performed, removing an intact simple cyst that was found to contain a smaller benign teratoma. Blood was still oozing slightly from a corpus luteum of the right ovary that seemed to be the source of the hemorrhage. No procedure was performed on the right ovary. The patient recovered uneventfully and was restarted on a regimen of warfarin and was given birth control pills containing norethindrone and ethinyl estradiol (Modicon).

Comment.—Minor ovarian bleeding from interruption of ovarian capsule integrity during ovulation is a normal occurrence in young women. Although intracystic and corpus luteum bleeding are occasionally seen in patients receiving anticoagulant therapy, the occurrence of corpus luteum hemorrhage in this group of patients is potentially fatal.[1-8] In most of the reported cases, the diagnosis was not made early, and the patient underwent exploratory laparotomy because of hemorrhagic shock. Our patient's condition was stabilized by rapidly normalizing the prothrombin time and replacing lost blood. Once hemorrhage was controlled, low-dose heparin therapy[9,10] was started to provide anticoagulant protection prior to elective surgery for removal of the ovarian dermoid cyst. At operation, corpus luteum hemorrhage was confirmed.

Although hemorrhagic complications are more commonly seen in patients with a prolonged prothrombin time, massive corpus luteum hemorrhage and even death may occur in patients whose prothrombin times are in the therapeutic range (1.5 to 2.5 times the control values).[8]

Prevention of corpus luteum hemorrhage can be achieved by preventing ovulation. An oral contraceptive was used in the present case. Unfortunately, there are no studies of the effect of birth control pills on patients taking anticoagulants. The relationship between oral contraceptives and venous thrombosis remains controversial. There are increases in measured clotting factors in users of oral contraceptives that are similar to, but less pronounced than, the increases noted with pregnancy.[11] Several studies have suggested that exogenous estrogen treatment or pregnancy are causally related to venous thrombosis and thromboembolism.[12,13] However, a recent review of the subject indicated that claims of an increased risk of venous thromboembolism for patients using oral contraceptives are not justified.[11] We do not wish to ignore the potential risk of thrombosis possibly associated with the use of oral contraceptives or the interaction of oral contraceptives with anticoagulant therapy, potentially complicating management. However, given the current state of understanding, we believe that it is reasonable to use oral contraceptives combined with close monitoring of the prothrombin time in an attempt to prevent recurrence of corpus luteum hemorrhage.

Physicians caring for ovulating adolescents should be aware of potential causes of serious intra-abdominal bleeding related to the reproductive organs. Ectopic pregnancy must be considered and ruled out by appropriate diagnostic tests such as an assay for human chorionic gonadotropin. Corpus luteum hemorrhage in patients taking oral anticoagulants is a potentially fatal occurrence.

Eye Involvement in Anaphylactoid Purpura

We have recently observed a patient with an unusually protracted course of anaphylactoid purpura in whom recurrent eye involvement was an unusual feature. Various types of CNS involvement have been uncommonly reported in anaphylactoid purpura.[1-3] However, we have been unable to find a report of recurrent and symptomatic eye involvement in anaphylactoid purpura.

Report of a Case.—A 14-year-old girl had acute multiple joint involvement with swelling of her knees, ankles, and right wrist. At the same time, results of a urinalysis showed microscopic hematuria. Approximately two weeks after the onset of her joint symptoms, numerous small 1- to 2-mm macular lesions were noted on the lower extremities and buttocks. Two weeks later, she had crampy abdominal pain, melena, and gross blood in her stools.

Physical examination at that time showed a pale, irritable girl in moderate distress. A diffuse maculopapular rash was noted, involving the lower extremities and buttocks. Ecchymotic areas developed subsequently within these lesions. Discrete petechial lesions were noted in the same distribution. The petechial lesions in some areas coalesced into purpuric lesions. One isolated purpuric lesion was noted on the forehead. The trunk, abdomen, back, and arms were spared the rash. Pedal edema and erythema of the dorsum of the right foot was present. Examination of her abdomen showed diffuse, moderate tenderness

but no localizing signs and no organomegaly.

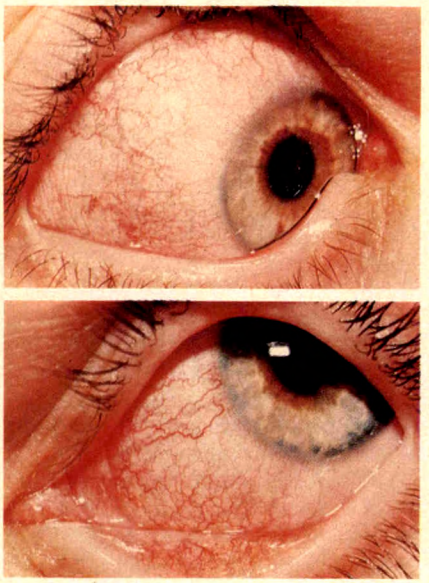
Laboratory studies showed a hemoglobin level of 13.4 g/dL, with a hematocrit reading of 42.2%. The WBC count was 12,000/cu mm, with a normal differential. The platelet count was 295,000/cu mm. The ESR was 12 mm/hr. Urinalysis showed proteinuria (2+), with 50 RBCs per high-power field. No casts were seen in the urinary sediment. A 20-channel automated serum chemistry profile showed no abnormalities. The BUN value was 11 mg/dL, and the serum creatinine level was 0.8 mg/dL. Streptozyme, C-reactive protein, and lupus erythematosus preparation tests were negative. Her β_{1c} globulin level was 72 mg/dL (normal value, 55 to 120 mg/dL). The prothrombin time was 10.8 s, with a control of 11.4 s, and partial thromboplastin time was 30.1 s, with a control of 31.5 s. Serum for anti-DNA antibodies showed less than 1 μg DNA-bound per milliliter.

Eye involvement was first noted approximately five weeks after onset of her joint symptoms and was manifested by photophobia, intermittent pain in the eyes, and eye findings as shown in the Figure. Ophthalmologic evaluation showed deep, vascular engorgement of episcleral vessels in all quadrants of both eyes. There was excessive tearing associated with photophobia. There was no staining of the corneal epithelium, and the anterior chambers were clear. Extraocular movements, pupils, and fundi were all within normal limits. Vision was correctable to 20/20 in each eye. The findings were compatible with a vasculitis involving the vessels of the episcleral region.

The patient's clinical course was marked by severe polyarthralgia, with edema over the joints of the lower extremities. Because of severe joint pain unresponsive to analgesics, corticosteroid therapy was started with prednisone in a dosage of 60 mg daily. During the next six days, there was rapid resolution of her joint symptoms, skin rash, and eye involvement. She was switched to a regimen of prednisone given as a single 60-mg dose on alternate days and a schedule outlined to gradually decrease and then discontinue the prednisone therapy during a period of four weeks.

For the next seven months, the patient's course was one of multiple exacerbations of joint, skin, and eye manifestations whenever her prednisone dose was decreased to less than 30 mg on alternate days. The joint, skin, and eye involvement remained sensitive to daily prednisone administration. All of the nonrenal manifestations resolved within three to five days of reinstitution of daily prednisone therapy. Throughout this time period, she continued to show moderate proteinuria and microscopic hematuria.

Ten months after onset of her disease process, steroid therapy was finally discontinued. During the six-month period after discontinuation of prednisone to the present, she has had three mild episodes of joint pain and eye involvement that was manifested by injection of the scleral vessels and by photophobia. None of these have been severe enough to require reinstitution of steroid therapy and have spontaneously remitted. Her urine remains abnormal, with microscopic hematuria and proteinuria (2 to 3+). However, her BUN and creatinine levels are within the normal ranges for age.



Eye involvement showing right eye (top) and left eye (bottom).

Comment.—Our patient had no history of eye disease other than a refractive error. The temporal relationship of the eye involvement to the other classic findings of anaphylactoid purpura, especially her joint and skin manifestations, suggests that her eye involvement was an integral part of her disease process. This association is also suggested by the prompt resolution of the ophthalmic signs and symptoms with prednisone therapy. The eye manifestations always responded simultaneously with her other symptoms, joint and skin, which were steroid-sensitive. We have been unable to find a previous report of similar ophthalmic involvement in anaphylactoid purpura. Ryder and Marcus[2] have reported a case in which there was transient conjugate eye deviation, cortical blindness, and convulsions associated with anaphylactoid purpura.

Involvement of the CNS with anaphylactoid purpura has been noted as one of the less common manifestations.[1-3] Convulsions have been reported secondary to hypertensive encephalopathy as well as presumed secondary to direct CNS involvement in the disease process.[3] Lewis and Philpott[3] have reported hemiplegia, presumably secondary to cerebral thrombosis or hemorrhage. Additionally, they have reported subarachnoid hemorrhage with uneventful recovery. Our patient has had no other manifestations of CNS involvement during the course of her illness. The basic pathologic process in anaphylactoid purpura seems to be a vasculitis that is characterized by small-vessel involvement with leukocytic perivascular infiltration and thrombosis. An immunologic basis has been suggested by the finding of immunoglobulin, complement, and fibrinogen deposition in capillary walls and connective tissue in skin biopsy specimens taken from affected areas.[4] Similarly, IgA, IgG, IgM and C3 have been noted frequently in the glomerulus of patients with anaphylactoid purpura nephritis.[4,5]

The eye manifestations in our patient are compatible with the basic pathologic process being a vasculitis involving small superficial vessels. Anatomically, the episcleral vessels are similar to the small vessels typically involved in the skin lesions of anaphylactoid purpura. Clinically, the engorgement of the episcleral vessels as well as the symptoms of photophobia and pain were in association with other major manifestations of anaphylactoid purpura such as joint and skin involvement. The prompt resolution of her eye symptoms with institution of daily prednisone therapy is typical of the nonrenal manifestations of anaphylactoid therapy.

Letters to the Editor

Chronic 'Diarrhea' and Diet

Sir.—The article by Cohen et al on "Chronic Nonspecific Diarrhea" (JOURNAL 133:490-492, 1979) contains some disturbing concepts and raises important questions.

What is "diarrhea"? What is the normal stool pattern of humans who consume diets rich in fruit and other fibers? The five children reported were receiving diets that in most respects correspond exactly to those recommended as "dietary goals for the United States": increased consumption of complex carbohydrates and "naturally occurring" sugars, from about 28% of energy intake to about 48% of energy intake; reduced overall fat consumption, from approximately 40% to about 30% of energy intake; reduced saturated fat consumption, to about 10% of total energy intake. This is supposed to be accomplished by increased consumption of fruits, vegetables, and whole grains; by decreased consumption of foods rich in total fat, and partial replacement of saturated fats with polyunsaturated fat; by decreased consumption of animal fat, except for young children; by substitution of low-fat and nonfat milk for whole milk, and low-fat dairy products for high-fat dairy products; and by decreased consumption of butter-fat, eggs, and other foods rich in cholesterol. The result of these changes was that, instead of the small, constipated stools typical of developed societies, these children had the more frequent, mushy, sometimes liquid stools that are characteristic of the remaining 90% of the world's population. Despite these changes, the children continued to grow perfectly well. The fact that they did grow at a much better rate than that characteristic of children in developing countries, despite a relatively "low" fat intake, means that the mothers were indeed successful in increasing their intake of the recommended high-fiber, high-complex carbohydrate foods to rather high levels. Is this bad? Is it abnormal? Does it require a work-up for malabsorption? Does everyone in this country have to conform, even in the nature of their stools?

Case 1 was receiving 22% of total calories as fat; case 2 was consuming 25 g of fat per day; case 3 was consuming 16% of total calories as fat; case 4 was consuming 26% of total calories as fat; in the process of being worked up, case 5 was given a "normal" fat intake of 50 g/day, and then the family was counselled to change the family diet to a higher, more appropriate level of fat intake. The fat intakes of these children, when they were being "deprived" of fat, were higher than those of 90% of the world's children.

The wisdom and the scientific validity of the national dietary "goals" are much in debate, but many in the nutrition community believe that there is enough evidence to make it at least prudent to follow the recommendations. Who is to say that the mothers in question were not doing the right thing? And what harm was being done to their children?

The attribution of the frequent, mushy stools to a low fat intake in purely arbitrary. No evidence is put forth to support such a concept. The authors claim that the simple addition of fat to the diet cured the "diarrhea" and that this was accomplished without decreasing the carbohydrate content of the diets. This sounds most unlikely, as the addition of so many fat calories must of necessity have resulted in a decrease in the intake of the high-fiber, high-complex carbohydrate foods. It seems much more likely to me, on the basis of extensive experience with the feeding of such diets, that the high-fiber intake was responsible for the frequent, mushy stools and that its decrease "corrected" these to the normal, constipated stool of our society. In at least two, possibly three of the cases, there were "relapses" when the diet was altered in the direction of higher fiber intakes.

GEORGE G. GRAHAM, MD
Division of Human Nutrition
The Johns Hopkins University
615 N Wolf St
Baltimore, MD 21205

In Reply.—Dr Graham's interest in and comments on our work are appreciated. As our attention focuses increasingly on diet and other environmental factors that affect disease states, we agree that we must exert great care attributing these relationships to cause and effect. This is particularly important in an era when nutritional data evolve into national policy.

Abnormal bowel movements have been characterized as disease states since the second century AD, when Arataeus described diarrhea as "the discharge of undigested food in a fluid state." Attempts to quantify diarrhea more precisely have met with little success, since "normal" bowel function differs for each person. Even the best index, stool weight, cannot suffice, particularly in cross-cultural comparisons.[1] Thus, one cannot use these measures alone to standardize what is diarrhea and what is not. One must evaluate the change in stool pattern for the individual patient.

The patients described in our report were documented as having diarrhea at the time of presentation as defined by some of the criteria used by Dr Graham and his co-workers[3] ("loose stools of increased number") and by parents of the patients ("when you have to change their socks as well as their diapers"). The stool pattern of these patients after the institution of the dietary regimen was improved to the point of having the fewer and less liquid (soft, semiformed) stools characteristic of normal bowel function. Constipation did not develop in any of the patients.

These chronic diarrheal symptoms may occur in the absence of malabsorption or failure to thrive, because the loss of calories may not be as prominent as the loss of water and solute. Diagnostic and therapeutic measures are obviously important to rule out even more portentious ailments and to appropriately relieve the symptoms (as well as to lessen the laundering of dirty socks).

Chronic nonspecific diarrhea (CNSD) is one of the most common causes of recurrent diarrhea and has been seen both with and without failure to thrive.[4] There is little doubt that it is still a heterologous category of patients with various causes for their symptoms. The pathogenesis of CNSD, and further evidence to implicate fat intake as a major factor and the possible mechanisms of actions, are discussed elsewhere.[5,6] The relationship of dietary fiber and stool

pattern in CNSD is only beginning to be evaluated. Although we did not investigate fiber content in the diets of these patients,[2] we have done so in six subsequent patients with CNSD that responded to our regimen. In those six patients, levels of dietary crude fiber and complex carbohydrates remained the same or actually increased along with the rise in dietary fat content. Where a fall in carbohydrate calories occurred at the expense of the fat increase, the decrease in carbohydrate levels primarily involved monosaccharides and disaccharides. However, there was no consistent pattern in either simple carbohydrate consumption or the relationship of fiber intake to relapse.

Certainly more laboratory and clinical research is needed to elucidate dietary as well as other factors relating to CNSD. At present, chronic recurrent diarrhea continues to be a clinically important syndrome, needing appropriate evaluation and treatment.

Triplo-X and Down Syndrome

Sir.—Gardner in the JOURNAL (133:253-254, 1979) reviewed case reports showing polysomy-X masquerading as Down syndrome.[1] Specifically, persons with XXXX, XXXXX, and XXXXY karyotypes were reported to resemble children with trisomy 21 syndrome. Triplo-X (47XXX) may be added to this list. We have seen a retarded teenage girl who had this karyotype and a suggestive, Down-like facies.[1] A. R. Robinson, MD, pointed out in conversation (November 1979) that children with 47XXX ascertained by newborn screening have also shown an increased incidence of epicanthal folds and clinodactyly, and resemble children with Down syndrome.[2]

Misdiagnosis of polysomy-X is, of course, not the only reason to perform a karyotype on every child with Down syndrome. Approximately 5% of these patients will have a translocation, half of whom have a parent who is a balanced carrier. A karyotype is mandatory for accurate genetic counseling regardless of maternal age.

The term Down syndrome is the nomenclature presently accepted by geneticists, indicating that Dr Down neither had nor owned the condition.

GENTRY W. YEATMAN, MD
Adolescent Medicine Service

2. Robinson AR, Lubs HA, Nielson J, et al: Summary of clinical findings: Profiles of children with 47XXY, 47XXX, and 47SYY karyotypes. *Birth Defects* 15:261, 1979.

In Reply.—Major Yeatman adds another clinical example of polysomy-X masquerading as Down's syndrome. The reference to the publication of Robinson et al is welcome, since it had not been published when I did my review. I take exception to Major Yeatman's facetious last sentence concerning the eponym derived from Dr Down's surname. His statement that "... Down syndrome is the nomenclature presently accepted by geneticists..." is inaccurate. The situation is a very mixed one, as indicated by the fact that in journals such as *Clinical Genetics* and the *Journal of Medical Genetics* one sees "Down's syndrome" used, as well as in a genetics textbook such as Levitan and Montagu's *Textbook of Human Genetics*. *The Lancet* is ambivalent: "Down syndrome"[1] appears to be favored now, but it still uses "Burkitt's lymphoma"![2] Eponyms with multiple surnames have never lent themselves to the use of the possessive, such as Prader-Willi syndrome or Laurence-Moon-Biedl-Bardet syndrome. Although writers of stylebooks and committees may issue edicts that eponyms will be used without the possessive, it remains for the spoken language to pass judgment on this. As the Académie Française has found out, the spoken language has a life of its own. If the linguistic mutation "Down syndrome" has survival value, it will be accepted eventually. I will know that time has arrived when the layman says "Bright disease" instead of "Bright's disease."

Circumcision and Patient Education

Sir.—We read with interest the article on circumcision by Herrera and Trouern-Trend (JOURNAL 133:1069-1070, 1979). Because there are "no medical indications for routine circumcision,"[1,2] counseling parents to ensure informed consent is both difficult and time-consuming. To facilitate counseling, we prepared a handout for parents on newborn circumcision. The literature was extensively reviewed and special efforts were taken to present both the advantages and disadvantages of the procedure. Illustrations, and information on proper hygiene of the uncircumcised penis are also included. The parents are asked to sign a statement indicating that they have read and understand the information provided in the handout. The parents are then counseled by the attending physician. This use of printed educational materials has resulted in a marked reduction in physician time required to ensure informed consent and has also been associated with a 30% reduction in our neonatal circumcision rate.

Books

Pediatric Respiratory Therapy, ed 2, by Marvin D. Lough, Carl F. Doershuk, and Robert C. Stern, 313 pp, Chicago, Year Book Medical Publishers, 1979.

The new, second edition of this volume is a very useful and well-written combination of practical information and advice, with brief summaries of relevant clinical and pathophysiological background information. With contributions by 14 authors, this book should be of most interest to students and practitioners involved directly or indirectly in the respiratory care of children. This edition includes three new chapters and incorporates much of the relevant new understanding, techniques, and equipment that have emerged in five years since the first edition was published.

Development of the cardiopulmonary systems, the pulmonary defense systems, and some nonmetabolic functions of the lung are concisely reviewed in the first two chapters. Some specific diseases and congenital defects that result from or cause abnormalities in these normal patterns are also presented. All the uniquely neonatal clinical, pathophysiological, and therapeutic relevant background information and aspects or respiratory care are contained in chapter 3. A valuable new chapter on pulmonary aspects of cardiovascular disease clearly explains some of the mechanisms by which diseases of the heart and the pulmonary circulation can cause signs and symptoms that are commonly associated with respiratory disease, such as tachypnea and wheezing. Diagrams and tables are effectively used to illustrate the pathophysiology of various congenital heart lesions.

There are three chapters devoted specifically to various aspects of respiratory therapy, which cover such topics as guidelines on organization and administration of a respiratory therapy service, and some practical hints on how to work successfully with children. In addition, the advantages and disadvantages of aerosols, oxygen, intermittent positive pressure breathing (IPPB), different types of mechanical ventilators, and approaches to cleaning respiratory equipment are also discussed. Unfortunately, the authors have avoided any specific mention of the tedious problems involved in effectively cleaning pulmonary function equipment, such as spirometers.

"Diagnostic and Therapeutic Procedures in Pediatric Respiratory Disease" is another new chapter, which contains practical summaries of important aspects of procedures, such as tracheal intubation, thoracentesis, percutaneous lung aspiration, and various radiologic procedures. I disagree, however, with the author's indirect recommendation of oily Dionosil as the "most popular" contrast material for bronchograms, since sterile barium sulfate solution yields excellent results and is less irritating to the respiratory mucosa.

Finally, there are two chapters concerned with pulmonary function testing (including blood gas sampling and exercise testing) in children. The discussion includes hints for obtaining cooperation in young subjects, the effects of growth on lung fuction, and general guidelines for interpretation of test results.

In summary, this is a well-edited, practically oriented book that is highly recommended for pediatric respiratory care practitioners, since it combines concise discussions of appropriately selected clinical, procedural, and theoretical material most relevant to their daily activities. It is generally up-to-date and accurate (there are some minor points I would take issue with, such as the statement that IPPB is effective treatment for pulmonary infection and hypoxia, and the unqualified mention of the use of antibiotic aerosols). The three chapters that are new to this second edition further enhance the value of this most useful publication.

Ultrasound in Pediatrics, edited by Murray Miskin, K. R. Bloom, B. B. Goldberg, et al, 337 pp, $29.50, New York, Grune & Stratton Inc, 1979.

Ultrasound in Pediatrics is an excellent compilation of the application of ultrasound to five areas in pediatrics. It is not encyclopedic or comprehensive in scope, but in being "directed toward the practitioner of general diagnostic ultrasound, to residents and fellows obtaining training in that specialty and to practitioners of pediatric medicine and surgery," it offers a very useful introduction to this diagnostic method.

The volume is edited by Dr Murray Miskin, who also has contributed the introduction and chapter 6, "Gynecologic Ultrasonography." The other four chapters are contributed by individuals with substantial experience in specific areas of sonography application.

The introduction emphasizes the vast potentiality of ultrasound in the assessment of pediatric patients. "Although no ionizing radiation is used in ultrasonography, it is a modality that introduces mechanical energy into the patient's body" (that is, it is "invasive"), but without deleterious effects at the energy levels utilized. Nevertheless, the designation "noninvasive" is used elsewhere in the book by other contributors and even the editor. The painless feature of ultrasound is a tremendous boon, because the ultrasonographer need not be concerned about inflicting pain on a child and as a result it is easier to get the child to cooperate.

Chapter 2, "Pediatric Sonoencephalography," is the longest of the chapters (152 pages) and the most detailed with 76 figures. It includes applications of A-mode and B-mode methods. In Fig 2-20, a useful graph of ventricular size vs age in 100 pediatric patients is offered. Normal anatomy of the brain and many clinical entities

as manifested by sonoencephalography are described.

Chapter 3, "Pediatric Echocardiography," introduces the recent development of two-dimensional echocardiograms in real time, but the descriptions and figures are via the single crystal examination. The 109 references to this chapter provide comprehensive source material for those especially interested.

Chapter 4, "Abdominal Ultrasound," is also well referenced (91 references) and illustrated (44 figures). The quality of the sonographic pictures is excellent. The chapter includes a section on retroperitoneal structures and to some extent overlaps with chapter 5.

Chapter 5, "Retroperitoneal Ultrasonography," describes useful technical details, some of which are applicable to the abdomen in general. Sonographic images in this chapter are clear and many are correlated with radiologic findings of intravenous urography. Applications of ultrasound in cyst aspiration and in solid lesion biopsy are included.

Chapter 6, "Gynecologic Ultrasonography," follows the format of other chapters in considerations of technique, normal anatomy, and categories of disease. A summary on embryology of the region is offered "to refresh the reader's memory concerning abnormalities that have an embryologic basis."

Ultrasound in Pediatrics is a very useful introductory book that contains a wealth of information in its 337 pages, in its 190 figures containing 397 sonographic pictures, 67 radiologic pictures, 14 drawings, 3 photographic pictures, and 1 graph, and in its three tables. It is a highly recommended addition to pediatric libraries.

Laryngo-tracheal Problems in the Pediatric Patient, edited by Gerald B. Healy and Trevor J. I. McGill, 129 pp, $13.75, Springfield, Ill, Charles C Thomas Publisher, 1979.

Laryngotracheal diseases of the infant and child can be a potential threat to life, are often difficult to assess, and not infrequently are poorly understood. This book is therefore timely and welcome. It is a slender volume consisting of a series of monographs and two panel discussions by distinguished contributors from the various disciplines of otolaryngology, pediatrics, radiology, anesthesia, and surgery.

The text is introduced with an enlightening discussion of the special anatomical features of the infant larynx that make it so susceptible to obstruction. The middle chapters contain the major body of information so far as the practicing pediatrician is concerned. They deal with the topics of the differential diagnosis of upper airway obstruction, radiological considerations of laryngotracheal problems, inflammatory diseases of the larynx, the team approach to epiglottitis, anesthetic management of epiglottitis, congenital anomalies of the larynx, and subglottic stenosis. These sections are concise, lucid, and comprehensive. The laryngeal photographs and roentgenograms are well done. An unfortunate lapse is the absence of discussion in any of these chapters of foreign bodies lodged in the upper airway.

A following chapter is entitled "Tracheal Considerations in Upper Airway Obstruction." It is an expertly rendered and nicely illustrated treatise on vascular rings. It would have been more comprehensive and closer to its title had some mention been made of congenital tracheal narrowing, laryngotracheal clefts, and tracheoesophageal fistulae. The former condition is rare, and the latter two are not primarily obstructive problems but certainly complicate the newborn airway.

Next is a chapter devoted to respiratory papillomatosis with emphasis on treatment with carbon dioxide laser. This is probably of greatest interest to otolaryngologists with special interest in pediatric airway problems.

The final two chapters are panel discussions dealing with the management of acute inflammatory obstruction and management of artificial airways. They represent the spontaneous comments of the participants and are perforce somewhat discursive and tendentious. Nevertheless, they contain valuable insights of highly experienced clinicians.

The unique appeal of this volume lies in the fact that it successfully collates under a single cover the individual perspectives of all the disciplines involved in the diagnosis and management of diseases that threaten the pediatric airway. It provides valuable guidelines for all charged with the management of this problem and is well worth its modest price.

Genetic Diseases and Developmental Disabilities: Aspects of Detection and Prevention, edited by Tamah L. Sadick and Siegfried M. Pueschel, 134 pp, $12.50, Boulder, Colo, Westview Press, 1979.

This is a collection of papers presented at the 144th annual meeting of the American Association for the Advancement of Science (AAAS), Feb 13, 1978, in Washington, DC. The state of the art as of that date was reviewed by the following speakers: Barton Childs on genetics and preventive medicine, and genetics and health education; Charles R. Scriver on genetic screening—the heterozygote experience; Robert Guthrie on screening of newborn infants; Richard C. Talamo on screening for α_1-antitrypsin deficiency; Marie Louise E. Lubs on carrier detection in Duchenne's muscular dystrophy and implications for genetic counseling in X-linked disease; Siegfried M. Pueschel on prenatal diagnosis of chromosomal disorders; Aubrey Milunsky (as summarized by Tamah L. Sadick) on prenatal detection of neural tube defects; Maurice J. Mahoney and John C. Hobbins on prenatal diagnosis by fetoscopy and fetal blood sampling; and David G. Nathan on prenatal diagnosis of the hemoglobinopathies. The phrase "developmental disabilities" in the title of the book does not seem very relevant to its contents.

The final chapter of the book, Barton Childs' discussion of genetics and health education, had previously appeared in the *American Journal of Human Genetics* in 1974. As might be expected when papers presented at a meeting are recorded, there is an uneven quality about the book. This is probably unavoidable. Some chapters are finished products, such as those by Childs and by Scriver, and others are in the nature of abstracts. The chapter on prenatal diagnosis of chromosomal disorders is mostly about counseling for amniocentesis and contains little of interest with regard to cytogenetics. Nevertheless, the intent of the AAAS in fostering rapid dissemina-

tion of information is served, even though some presentations seem to be rather rough transcriptions of talks.

Every effort apparently was made to speed publication, as the book was printed by offset directly from the authors' typescript copy. The right margins are not even.

This volume certainly would not be suitable as a textbook devoted to the topics listed earlier, but it does serve to bring to the reader up-to-date current information in certain of the areas listed in the table of contents.

Feed Your Kids Right, by Lendon Smith, MD, 251 pp, $9.95, New York, McGraw-Hill Book Co, 1979.

This book should not be recommended to patients or their parents. Although many of the statements in the book are based on nutritional evidence, these are counterbalanced by dogmatic pronouncements based on beliefs, half-truths, or untruths.

The casual reader may enjoy some new definitions, eg, antinutrient as a substance that increases the body's need for more nutrients and vitamins, "which are really concentrated foods." Some may enjoy such homilies as "children usually hate vitamins because the B vitamins especially taste like moldy dirt" or "certified raw milk comes from better-fed cows."

Not so amusing or petty, however, are the author's "Five Levels of Health," the apparent basis of his doctrine. These are defined by general activity, irritability, how the child does in school, how the child cuts teeth, and others. Any parents whose child is not absolutely perfect can easily read that they are to blame for feeding the child poorly. Further, if they decide that their child's condition can be placed in one of these five categories, they may well delay diagnosis and treatment while not sparing considerable expense. The recommended use of injections of B complex is mind boggling. The workup for patients who do not get better even after vitamin shots, fasting, and recommendation for psychotherapy is a hair analysis.

In no place in the book can one find data to support the author's unorthodox nutritional approach to disease prevention. The complex stress formula for adrenal support may well have some beneficial effects. However, it would be simpler and less expensive to obtain than by a sugar-free diet (though he allows fructose without explanation), 10 g of vitamin C, vitamin B complex at 200 mg/day, 3 g of pantothenic acid, 500 mg of pyridoxine, 50,000 units of vitamin A, and calcium at 1 g/day. Again, the vitamin C and B complex frequently need be given by injection.

The author's allergy program is similar in many respects to that of Dr William Crook (who has attempted to quantitate effects), such as avoidance of hypoglycemia and foreign substances in the Feingold diet, but its effects are undocumented. The author says it is effective.

Like others who have successfully sold snake oil and cured ill patients, these dicta will work for some. It is estimated that 95% of patients recover regardless of treatment. The author's percentage is probably no lower. The antiscientific and antiacademic approach is best summed up in the author's lack of humility: "biochemistry has now advanced to the state where all the important chemicals needed by the body and present in foods are known." If this is a book of faith, as stated in the final chapter, this should be stated on the flyleaf and at the beginning of the text so that readers are made aware of what they are about to read.

Bone Dysplasias of Infancy, by Bryan J. Cremin and Peter Beighton, 107 pp, with illus, $39, New York, Springer-Verlag, 1978.

Here the authors have attempted to produce a concise atlas of relevant information concerning bone dysplasias identifiable at birth. They have been moderately successful. Most of the case material is derived from practical experience in the departments of Radiology and Genetics, the University of Capetown Medical School, South Africa. There are 50 figures containing 107 radiographic pictures, 12 clinical pictures, two schematic diagrams, one sonographic picture, and one line drawing. References at the end of each chapter are limited to recent specific articles and general reviews. A short list of other relevant references and monographs is listed in the appendix. The atlas uses both the 1969 and the revised 1977 *Paris Nomenclature for Constitutional Diseases of Bone* for terminology and for chapter arrangement of specific dysplasias. A brief and superficial glossary of useful terms is included. Although the skeletal dysplasias differ widely in their complications and prognoses, they are all heritable conditions with a specific recurrence risk.

The clinical evaluation part of chapter 1 is limited, being only a listing of various dysplasias in degree of lethality and of four clinical features neither consistent nor specific as diagnostic indicators. The statements on genetic evaluation, genetic counseling, and antenatal diagnosis are appropriately basic information. Good schematic diagrams of the mechanisms of autosomal dominant and recessive inheritance are included.

Radiographic techniques are described in chapter 2 under subheadings of "Antenatal Radiology," "Ultrasonography," "Amniography and Fetography," "Postnatal Radiography," "Examination of the Prenatal Radiographs," "Multidisciplinary Evaluation," and "Postmortem Staining Techniques." Noteworthy are the following points. Ultrasonography is preferred for assessment of fetal maturity and position and is capable of detecting gross abnormalities especially in the presence of hydramnios. Radiography is considered the superior diagnostic method for discovering bone dysplasias in the third trimester of pregnancy. Although "multidisciplinary evaluation" is an excellent idea, the authors do not elaborate, but are supportive of the modus operandi of Spranger, a pediatrician, in evaluation of dysplasias: "a. Do not diagnose from a single sign, diagnosis must be made from a pattern; b. Never diagnose from a single site, a skeletal survey is necessary; c. Have patience if you can't make the diagnosis in infancy, the pattern may take time to evolve; d. Lastly, do not publish too early as a single case may only add to confusion."

Chapters 3 to 19 each address a specific dysplastic condition. Noteworthy are the following points. (1) Two types of achondrogenesis have been described, the difference between each being essentially radiological. (2) Thanatophoric dysplasia is the most common form of fetal neonatal

dwarfism and a "cloverleaf" skull may be an associated finding. (3) Patients who survive asphyxiating thoracic dysplasia tend to outgrow the radiographic changes in their long bones and pelves. (4) There are three types of lethal short-rib polydactyly syndrome. Type 3 (Naumoff) is characterized by radiographic signs of severely shortened tubular bones with terminal spurs and a small cranial base. (5) Mesomelic dysplasia, type "Nievergelt," has a distinctive rhomboidal tibia. The authors give concise descriptions of the following dysplasias: chondroectodermal dysplasia, chondrodysplasia punctata, campomelic dysplasia, achondroplasia (most common form of disproportional dwarfism), diastrophic dysplasia, metatropic dysplasia, Kniest syndrome, spondyleopiphyseal dysplasia congenita, Larsen's syndrome, cleidocranial dysplasia, osteogenesis imperfecta congenita, hypophosphatasia, and osteopetrosis and other sclerosing bone dysplasias.

The concise atlas is useful because of its specificity to infancy. It should be a good preliminary reference source for workers in neonatology, pediatrics, genetics, and radiology. For more comprehensive information concerning bone dysplasias, other more detailed sources will be necessary.

Books in Brief

Combined Cumulative Index to Pediatrics, vol 1 (626 pp, $38, Buffalo, NY, Numarc Book Corp, 1979). Not all journals are in the habit of publishing a cumulative index, so this volume should be of help to those who wish to delve into the recent pediatric literature. Articles published during the years 1976 to 1978 in six American pediatric journals—*American Journal of Diseases of Children, Clinical Pediatrics, Journal of Pediatrics, Pediatric Annals, Pediatric Clinics of North America*, and *Pediatrics*—are listed here by author and by topic. The publishers state that additional volumes are to be forthcoming at three-year intervals, plus an annual supplement for each of the intervening years. The volume, and those promised for the future, should help to make the pediatric bibliophile's task an easier one, though one will have to look elsewhere for articles published in foreign pediatric journals.

Mendelian Inheritance in Man, ed 5, by Victor A. McKusick (975 pp, Baltimore, Johns Hopkins University Press, 1978) (price not stated). This is a complete compilation of human genetic traits and diseases, including anatomic, enzymatic, neurologic, hematologic, and even behavioral abnormalities. The vast number of entries are grouped into the three categories of dominant, recessive, and X-linked conditions. Many are accompanied by a brief discussion, and there are also brief sections devoted to HLA types, to chromosomal assignments for conditions where such is known, and to the increasing list of established enzymatic defects. This book is a most valuable source of information on human genetics. I could not help noting that the JOURNAL ranked high among the list of publications cited as sources for information included in this book.

The Influences of Maternal Hormones on the Fetus and Newborn, vol 5, *Pediatric and Adolescent Endocrinology*, edited by M. Nitzan (286 pp, New York, S Karger AG, 1979) (price not stated, paperback). This volume consists of 14 articles devoted to this general topic, including somatomedin, the sex hormones, catecholamines, prostaglandins, insulin, glucagon, thyroid, adrenal, and pituitary hormones. There is also a chapter about calcium metabolism during pregnancy. Of current interest is the discussion of the role of adrenal glucocorticoids in the maturation of fetal lung biochemistry and function. The role of the "anti-Müllerian" hormone (a hormone produced by the fetal testis, which acts to cause the Müllerian ducts to regress) is also briefly discussed. All in all, this is a fair presentation of current knowledge in this area.

Perinatal Medicine, vol 1 and 2, edited by E. Kerpel-Fronius, P. V. Véghelyi, and J. Rosta (1,449 pp, Budapest, Akadémiai Kiadó, 1978) (price not stated). This is a multiauthored and massive tome that covers the broad and rapidly expanding field of perinatology. The various aspects of this field are presented in considerable detail and, for the benefit of American readers, entirely in English. Prenatal factors, intrauterine diagnosis, circulatory, gastrointestinal, hematologic, metabolic, and infectious factors all receive full attention, as do pulmonary, CNS, and renal phenomena; the approach is truly encyclopedic. One disturbing feature is the all-too-brief account of nutrition.

Intoxications of the Nervous System, part 1, vol 36, *Handbook of Clinical Neurology*, edited by P. J. Vinken and G. W. Bruyn (570 pp, Amsterdam, North-Holland Publishing Co, 1979) (price not stated). One of a series regarding various aspects of neurology, this particular volume is of special interest to pediatricians because of its chapters about lead and mercury poisoning. John Graef writes about lead, reminding us that there are now about 3 million tons of lead smelted or burned each year in the northern hemisphere, which is about ten times the amount used 100 years ago. This chapter about the clinical aspects is followed by one about neuropathology by A. Hirano and M. Iwata (New York), including some striking electron microscopic preparations showing nuclear inclusions, swollen axons, presence of vacuoles, blood vessel damage, and red cell extravasation.

There are three chapters about mercury poisoning. The first two (by D. Marsh, Rochester, NY, and H. Shiraki, Tokyo) deal with organic mercury compounds, the Iraq tragedy of 1972, and Minamata disease in Japan; the third chapter (R. Kark, Los Angeles) deals with inorganic mercury, including acrodynia. Of importance is the fact that though both types of mercury compounds produce CNS symptoms, the spectrum of signs and symptoms differs. Of interest is the failure of observers of children with methylmercury poisoning to describe symptoms and signs of acrodynia. Not all individuals exposed to small amounts of inorganic mercury become ill, and Kark discusses the possibilities of genetic susceptibility and/or dietary predispositions. The remaining chapters are devoted to a variety of intoxicants: arsenic, manganese, mallium, tin, bromide, industrial solvents, methyl alcohol, glucosides, mushrooms, and ergot.

Rochester, NY 14642

Paediatric Endocrinologist wanted for position in the Department of Paediatrics, Faculty of Medicine at The University of Toronto. This is a fulltime academic position for a Certified Paediatrician also trained in Paediatric Endocrinology. Responsibilities will include patient care, undergraduate and graduate teaching and clinical research. The candidate must have a strong interest in Diabetes Mellitus. Salary to be negotiated. The post is at The Hospital for Sick Children, Toronto. Interested individuals should submit their curriculum vitaes to Dr. Robert M. Ehrlich, Professor of Paediatrics and Chief of the Division of Endocrinology, The Hospital for Sick Children, 555 University Avenue, Toronto, Ontario Canada, M5G 1X8.

CHAIRPERSON
DEPARTMENT OF PEDIATRICS
THE UNIVERSITY OF TENNESSEE
COLLEGE OF MEDICINE
KNOXVILLE UNIT

Full-time position as chairperson with major responsibilities in undergraduate, graduate and continuing medical education, research and patient care. Requires certification by the American Board of Pediatrics, experience in academic medicine and demonstrated leadership capabilities. Position available July 1, 1980. Salary and rank commensurate with education and experience.

Send curriculum vitae to:

a chance for a better life with Depakene®
Valproic Acid

For your patients with mixed seizures including absence, or pure absence

Effective seizure control[1] without cosmetic disfigurement

In 28 studies of patients with mixed grand mal and absence, 76% of all patients gained significant improvement; over one-third became seizure-free. In 60 studies involving pure absence, 86% of patients were improved; half became seizure-free.

While serious side effects, including fatal hepatitis, have occurred, the most common side effect with Depakene is G.I. upset, which usually responds to temporary dosage reduction. Problem sedation is not common and cosmetic stigmata such as gum hypertrophy and hirsutism do not occur.

A widely useful anticonvulsant

Depakene is indicated as sole or adjunctive therapy in both simple and complex absence seizures. It is also indicated for adjunctive treatment of patients with multiple seizure types which include absence. Clinical response has been especially noteworthy among patients with generalized tonic-clonic attacks, or with minor motor seizures (e.g., myoclonic movements, akinetic seizures), where combined with absence.

Offering your patients a chance for a better life

Sustained freedom from seizures can mean a drivers license, an active social schedule, involvement in athletic competition—a better life for your patient.

1. Worldwide studies of Depakene experience (Data refer only to grand mal and/or absence seizures. Since each type was evaluated separately, some patients appear in both groups. Though most of these studies were uncontrolled and had widely differing protocols, their collective data clearly support efficacy of the drug).

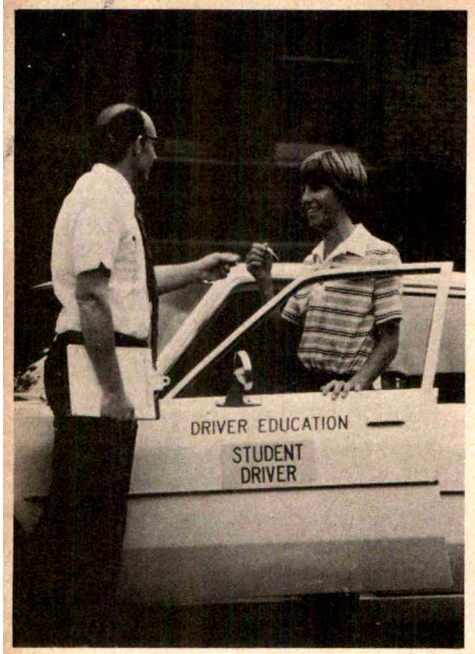
See overleaf for prescribing information

Abbott Laboratories,
North Chicago, Illinois 60064

0013326R2

Depakene®
Valproic Acid Capsules 250 mg
250 mg/5 ml syrup

Depakene®
Valproic Acid



Offering a chance for a better life for your patients with mixed seizures including absence, or pure absence

PRESCRIBING INFORMATION

INDICATIONS: DEPAKENE (valproic acid) is indicated for use as sole and adjunctive therapy in the treatment of simple and complex absence seizures, including petit mal. DEPAKENE may also be used adjunctively in patients with multiple seizure types which include absence seizures.

In accordance with the International Classification of Seizures, simple absence is defined as very brief clouding of the sensorium or loss of consciousness (lasting usually 2-15 seconds), accompanied by certain generalized epileptic discharges without other detectable clinical signs. Complex absence is the term used when other signs are also present.

CONTRAINDICATIONS: DEPAKENE (valproic acid) is contraindicated in patients with known hypersensitivity to the drug.

WARNINGS: Hepatic failure resulting in fatalities has occurred in patients receiving DEPAKENE. These incidences usually have occurred during the first six months of treatment with DEPAKENE. Liver function tests should be performed prior to therapy and at frequent intervals thereafter. Caution should be observed when administering DEPAKENE to patients with pre-existing hepatic disease.

The drug should be discontinued immediately in the presence of significant hepatic dysfunction, suspected or apparent. The frequency of adverse effects (particularly elevated liver enzymes) may increase with increasing dose. Therefore, the benefit gained by increased seizure control by increasing the dosage must be weighed against the increased incidence of adverse effects sometimes seen at higher dosages.

Usage in Pregnancy: THE EFFECTS OF DEPAKENE IN HUMAN PREGNANCY ARE UNKNOWN. ANIMAL STUDIES HAVE DEMONSTRATED TERATOGENICITY.

Studies in rats demonstrated placental transfer of the drug. Doses greater than 65 mg/kg/day given to pregnant rats and mice produced skeletal abnormalities in the offspring, primarily involving ribs and vertebrae; doses greater than 150 mg/kg/day given to pregnant rabbits produced fetal resorptions and (primarily) soft-tissue abnormalities in the offspring. In rats a dose-related delay in the onset of parturition was noted. Postnatal growth and survival of the progeny were adversely affected, particularly when drug administration spanned the entire gestation and early lactation period.

THERE ARE MULTIPLE REPORTS IN THE CLINICAL LITERATURE WHICH INDICATE THAT THE USE OF ANTICONVULSANT DRUGS DURING PREGNANCY RESULTS IN AN INCREASED INCIDENCE OF BIRTH DEFECTS IN THE OFFSPRING. ALTHOUGH DATA ARE MORE EXTENSIVE WITH RESPECT TO TRIMETHADIONE, PARAMETHADIONE, PHENYTOIN, AND PHENOBARBITAL, REPORTS INDICATE A POSSIBLE SIMILAR ASSOCIATION WITH THE USE OF OTHER ANTICONVULSANT DRUGS. THEREFORE, ANTICONVULSANT DRUGS SHOULD BE ADMINISTERED TO WOMEN OF CHILDBEARING POTENTIAL ONLY IF THEY ARE CLEARLY SHOWN TO BE ESSENTIAL IN THE MANAGEMENT OF THEIR SEIZURES.

Anticonvulsant drugs should not be discontinued in patients in whom the drug is administered to prevent major seizures because of the strong possibility of precipitating status epilepticus with attendant hypoxia and threat to life. In individual cases where the severity and frequency of the seizure disorder are such that the removal of medication does not pose a serious threat to the patient, discontinuation of the drug may be considered prior to and during pregnancy, although it cannot be said with any confidence that even minor seizures do not pose some hazard to the developing embryo or fetus.

The prescribing physician will wish to weigh these considerations in treating or counseling epileptic women of childbearing potential.

PRECAUTIONS: *Hepatic dysfunction:* See WARNINGS.

General: Because of reports of thrombocytopenia and platelet aggregation dysfunction, platelet counts and bleeding time determination are recommended before initiating therapy and at periodic intervals. It is recommended that patients receiving DEPAKENE be monitored for platelet count prior to planned surgery. Clinical evidence of hemorrhage, bruising or a disorder of hemostasis/coagulation is an indication for reduction of DEPAKENE dosage or withdrawal of therapy pending investigation.

Since DEPAKENE (valproic acid) may interact with concurrently administered anticonvulsant drugs, periodic serum level determinations of concomitant anticonvulsant drugs are recommended during the early course of therapy. (See Drug Interactions).

DEPAKENE is partially eliminated in the urine as a keto-metabolite which may lead to a false interpretation of the urine ketone test.

Information For Patients: Since DEPAKENE may produce CNS depression, especially when combined with another CNS depressant (e.g., alcohol), patients should be advised not to engage in hazardous occupations, such as driving an automobile or operating dangerous machinery, until it is known that they do not become drowsy from the drug.

Drug Interactions: DEPAKENE may potentiate the CNS depressant activity of alcohol.

THERE IS EVIDENCE THAT DEPAKENE MAY CAUSE AN INCREASE IN SERUM PHENOBARBITAL LEVELS, ALTHOUGH THE MECHANISM OF THE INTERACTION IS UNKNOWN. ALL PATIENTS RECEIVING CONCOMITANT BARBITURATE THERAPY SHOULD BE CLOSELY MONITORED FOR NEUROLOGICAL TOXICITY, SERUM BARBITURATE DRUG LEVELS OBTAINED, IF POSSIBLE, AND THE BARBITURATE DOSAGE DECREASED, IF APPROPRIATE.

Primidone is metabolized into a barbiturate and, therefore, may also be involved in a similar or identical interaction.

THERE IS CONFLICTING EVIDENCE REGARDING THE INTERACTION OF DEPAKENE WITH PHENYTOIN. IT IS NOT KNOWN IF THERE IS A CHANGE IN UNBOUND (FREE) PHENYTOIN SERUM CONCENTRATIONS. THE DOSAGE OF PHENYTOIN SHOULD BE ADJUSTED AS REQUIRED BY THE CLINICAL SITUATION.

THE CONCOMITANT USE OF VALPROIC ACID AND CLONAZEPAM MAY PRODUCE ABSENCE STATUS.

Caution is recommended when DEPAKENE (valproic acid) is administered with drugs affecting coagulation, e.g., aspirin and warfarin. (See ADVERSE REACTIONS).

Carcinogenesis, Mutagenesis: There has been insufficient study of the drug in animals to determine whether it has carcinogenic potential. Carcinogenicity studies in rats and mice are currently in progress.

Mutagenesis studies on DEPAKENE have been performed using bacterial and mammalian systems. These studies have provided no evidence of a mutagenic potential for DEPAKENE.

Pregnancy: See WARNINGS.

Nursing Mothers: DEPAKENE is excreted in breast milk. It is not known what effect this would have on a nursing infant. As a general rule, nursing should not be undertaken while a patient is receiving DEPAKENE.

Fertility: Chronic toxicity studies in juvenile and adult rats and dogs demonstrated reduced spermatogenesis and testicular atrophy at doses greater than 200 mg/kg/day in rats and greater than 90 mg/kg/day in dogs. Segment I fertility studies in rats have shown doses up to 350 mg/kg/day for 60 days to have no effect on fertility. THE EFFECT OF DEPAKENE (VALPROIC ACID) ON THE DEVELOPMENT OF THE TESTES AND ON SPERM PRODUCTION AND FERTILITY IN HUMANS IS UNKNOWN.

ADVERSE REACTIONS: Since DEPAKENE (valproic acid) has usually been used with other anticonvulsant drugs, it is not possible, in most cases, to determine whether the following adverse reactions can be ascribed to DEPAKENE alone, or the combination of drugs.

Gastrointestinal: The most commonly reported side effects at the initiation of therapy are nausea, vomiting and indigestion. These effects are usually transient and rarely require discontinuation of therapy. Diarrhea, abdominal cramps and constipation have been reported. Both anorexia with some weight loss and increased appetite with weight gain have also been reported.

CNS Effects: Sedative effects have been noted in patients receiving valproic acid alone but are found most often in patients receiving combination therapy. Sedation usually disappears upon reduction of other anticonvulsant medication. Ataxia, headache, nystagmus, diplopia, asterixis, "spots before eyes", tremor, dysarthria, dizziness, and incoordination have rarely been noted. Rare cases of coma have been noted in patients also on phenobarbital.

Dermatologic: Transient increases in hair loss have been observed. Skin rash and petechiae have rarely been noted.

Psychiatric: Emotional upset, depression, psychosis, aggression, hyperactivity and behavioral deterioration have been reported.

Musculoskeletal: Weakness has been reported.

Hematopoietic: Thrombocytopenia has been reported. Valproic acid inhibits the secondary phase of platelet aggregation. (See DRUG INTERACTIONS). This may be reflected in altered bleeding time. Bruising, hematoma formation and frank hemorrhage have been reported. Relative lymphocytosis and hypofibrinogenemia have been noted. Leukopenia and eosinophilia have also been reported.

Hepatic: Increases in serum alkaline phosphatase and elevations of serum glutamic oxaloacetic transaminase (SGOT) have been noted. Elevation of SGOT may be dose related. Elevations of SGPT and LDH have been noted less frequently. Isolated cases of severe hepatotoxicity have been reported but do not appear dose related. (See WARNINGS).

OVERDOSAGE: A single case of overdosage with valproic acid has been reported. After ingesting 36 grams in combination with phenobarbital and phenytoin, the patient presented in deep coma. An electroencephalogram recorded diffuse slowing, compatible with the state of consciousness. The patient made an uneventful recovery.

Since DEPAKENE is absorbed very rapidly, gastric lavage may be of limited value. General supportive measures should be applied with particular attention being given to the maintenance of adequate urinary output.

DOSAGE AND ADMINISTRATION: DEPAKENE (valproic acid) is administered orally. The recommended initial dose is 15 mg/kg/day, increasing at one week intervals by 5 to 10 mg/kg/day, until seizures are controlled or side effects preclude further increases. The maximum recommended dosage is 60 mg/kg/day. If the total daily dose exceeds 250 mg, it should be given in a divided regimen.

The frequency of adverse effects (particularly elevated liver enzymes) may increase with increasing dose. Therefore, the benefit gained by increased seizure control by increased dosage must be weighed against the increased incidence of adverse effects sometimes seen at higher doses.

The following table is a guide for the initial daily dose of DEPAKENE (valproic acid) (15 mg/kg/day):

Weight (kg)	Weight (lb)	Total Daily Dose (mg)	Number of Capsules or Teaspoonfuls of Syrup Dose 1	Dose 2	Dose 3
10 - 24.9	22 - 54.9	250	0	0	1
25 - 39.9	55 - 87.9	500	1	0	1
40 - 59.9	88 - 131.9	750	1	1	1
60 - 74.9	132 - 164.9	1,000	1	1	2
75 - 89.9	165 - 197.9	1,250	2	1	2

A good correlation has not been established between daily dose, serum level and therapeutic effect, however, therapeutic serum levels for most patients will range from 50 to 100 mcg/ml. Occasional patients may be controlled with serum levels lower or higher than this range.

As the DEPAKENE dosage is titrated upward, blood levels of phenobarbital and/or phenytoin may be affected. (See PRECAUTIONS).

Patients who experience G.I. irritation may benefit from administration of the drug with food or by slowly building up the dose from an initial low level.

THE CAPSULES SHOULD BE SWALLOWED WITHOUT CHEWING TO AVOID LOCAL IRRITATION OF THE MOUTH AND THROAT.

HOW SUPPLIED: DEPAKENE (valproic acid) is available as orange-colored soft gelatin capsules of 250 mg valproic acid in bottles of 100 capsules (**NDC** 0074-5681-13), and as a red syrup containing the equivalent of 250 mg valproic acid per 5 ml as the sodium salt in bottles of 16 ounces (**NDC** 0074-5682-16).

ABBOTT

Instructions for Authors

General Information.—Send manuscripts by first-class (**not** registered) mail to the Chief Editor, Gilbert B. Forbes, MD, Box 777, 601 Elmwood Ave, Rochester, NY 14642. Designate one author as correspondent and provide his/her address and telephone number. Manuscripts are received with the understanding that they are not under simultaneous consideration by another publication. Accepted manuscripts become the permanent property of the *American Journal of Diseases of Children* and may not be published elsewhere without permission from the publisher (AMA).

In view of the provisions of *The Copyright Revision Act of 1976*, effective Jan 1, 1978, the author(s) of manuscripts, letters to the editor, and book reviews accepted for publication in the JOURNAL will be required to sign and date the following statement: "In consideration of the AMA taking action in reviewing and editing my/our submission, the author(s) undersigned hereby transfers, assigns, or otherwise conveys all copyright ownership to the AMA in the event that such work is published by the AMA."

Manuscript Preparation.—All the elements of a manuscript must be submitted in **triplicate, double-spaced throughout**. Use heavy-duty white bond paper, 21.6 × 27.9 cm, and 4-cm margins. If a word processor is used, do not justify lines. The style of writing should conform to proper English usage and syntax. All measurements are to be in metric units, temperatures in Centigrade.

All accepted manuscripts are subject to copy editing. The corresponding author will receive an edited typescript and layout for approval. Forms for ordering reprints are included with the edited typescript. Proofs will be sent for approval if requested by the author and if printing deadlines permit. The author is responsible for all statements in his/her work, including changes made by the copy editor.

Titles.—Titles should be short, specific, and clear. They should not exceed 42 characters per line, including punctuation and spaces, and be limited to two lines. The title page should include the full names and academic affiliations of all authors, the address to which requests for reprints should be sent, and, if the manuscript was presented at a meeting, the name of the organization, place, and date on which it was read.

Abstract.—Provide an abstract (135-word maximum) of the article, including statement of the problem, method of study, results, and conclusions. The abstract replaces the summary.

Informed Consent.—Manuscripts reporting the results of experimental investigations on humans must include a statement to the effect that informed consent was obtained from the parents or guardians after the nature of the procedure(s) had been fully explained.

Clinical Memoranda.—Brief accounts of interesting observations and clinical situations. Limited to 800 words plus one table or illustration; abstract unnecessary. Submit in triplicate, double-spaced. Copyright assignment required.

Letters to the Editor.—Correspondence pertaining to material published in the JOURNAL. Limit 500 words. Submit in triplicate, double-spaced, and clearly marked "For publication." Copyright assignment required.

References.—List in order of their appearance in the text, and type double-spaced, in the following manner:

1. Applebaum MM, Thaler MM: Reye syndrome without initial hepatic involvement. *Am J Dis Child* 1977; 131:295-296.
2. Koller LR: *Ultraviolet Radiation*, ed 2. New York, John Wiley & Sons, 1965, 141-160.
3. Daughaday WH: The adenohypophysis, in Williams RH (ed): *Textbook of Endocrinology*, ed 5. Philadelphia, WB Saunders, 1974: 31-79.

Do not include unpublished data, personal communications, or manuscripts "in preparation" or "submitted" in the list of references. Such material, if essential, may be incorporated in the body of the article.

Illustrations.—Submit only high-contrast glossy prints in triplicate, unmounted and untrimmed. Preferred size is 12.7 × 17.3 cm (5 × 7 in). Figure number, name of first author, and arrow indicating "top" should be typed on a gummed label and affixed to the back of each illustration. Lettering must be legible after reduction to column size. Magnification and stain should be provided for histologic sections.

For illustrations in full color submit 35-mm, positive color transparencies, mounted in cardboard and carefully packaged. Do not submit glass-mounted transparencies; do not submit color prints. The fee is $275 for up to six square-finished color illustrations that can be arranged on one page. A letter of intent to pay the fee must accompany submission.

Legends.—Legends for illustrations should be typed double-spaced, beginning on a separate sheet of paper (40-word maximum for each).

Acknowledgments.—Illustrations and tables from other publications must be suitably acknowledged, and accompanied by written permission from publisher and author.

Photographic Consents.—A signed statement of consent from **both** parents (or guardian) or the persons involved must accompany all photographs of patients in which a possibility of identification exists. It is not sufficient to cover the eyes to mask identity.

Tables.—Each table should be typed double-spaced, including all headings, on a separate sheet of 21.6 × 27.9 cm paper. If a table must be continued, use a second sheet and repeat all heads. Each table must have a title.

Uniform Requirements.—Further details on manuscript preparation are given in the document *Uniform Requirements for Manuscripts Submitted to Biomedical Journals* prepared by the International Steering Committee of Medical Editors. Reprints of this document are available by directing requests to this journal: Scientific Publications, 535 N Dearborn St, Chicago, IL 60610.

NOW PETER

Attention Deficit Disorders* under control...
His natural abilities are coming through

Now Peter's enjoying more things at play as well as in school. He works better with his teacher and classmates... likes doing things with his dad... gets more natural pleasure out of family and friends.

Now that his concentration is improved, his natural abilities are coming through. He's functioning better. Under a well-integrated program of treatment for Attention Deficit Disorders (ADD), hyperactivity and impulsiveness are markedly reduced.

Ritalin (methylphenidate) can be a vital part of his regimen. With adjunctive use of Ritalin, many ADD children are better able to control hyperkinetic behavior —act in a more natural and appropriate manner.

A 20-year record of proven efficacy

Over the years, Ritalin has become an established choice for pharmacotherapy of ADD. In a report by the

BEHAVES MORE NATURALLY.

National Council on Child Health,[1] Ritalin was described as among the most effective and best-documented agents for stimulant therapy in hyperkinetic children.

Reduces hyperactivity, impulsive behavior

Ritalin has a well-documented record of success in relieving the dominant symptoms of ADD. As it reduces distractibility, disorganized behavior and hyperactivity, improved school performance usually results,[2,3] as well as better peer interaction.[2]

Generally well tolerated

Although side effects may occur with Ritalin, they are generally not serious. During prolonged therapy, anorexia, weight loss, and insomnia are among the most frequently encountered adverse reactions. (See Adverse Reactions section of the prescribing information.) Even though most children require long-term treatment, there is little evidence of habituation.[1]

Therapy with Ritalin should be considered only after a medical diagnosis of ADD has been confirmed. Dosage can usually be interrupted during weekends and vacations. In some cases, these drug holidays reveal "stabilization" in the child's behavior without medication. They may permit a reduction in dosage and eventual discontinuation of drug therapy if warranted.

*Attention Deficit Disorders: new designation by the American Psychiatric Association; formerly called Minimal Brain Dysfunction (MBD) or Hyperkinetic Syndrome.

Ritalin . . . only when medication is indicated for Attention Deficit Disorders

Ritalin®
(methylphenidate)
as adjunctive therapy for ADD

Ritalin® C II
(methylphenidate)
Only when medication is indicated

Ritalin® hydrochloride (methylphenidate hydrochloride USP) C II

TABLETS

INDICATIONS

Attention Deficit Disorders (previously known as Minimal Brain Dysfunction in Children). Other terms being used to describe the behavioral syndrome below include: Hyperkinetic Child Syndrome, Minimal Brain Damage, Minimal Cerebral Dysfunction, Minor Cerebral Dysfunction.

Ritalin is indicated as an integral part of a total treatment program which typically includes other remedial measures (psychological, educational, social) for a stabilizing effect in children with a behavioral syndrome characterized by the following group of developmentally inappropriate symptoms: moderate-to-severe distractibility, short attention span, hyperactivity, emotional lability, and impulsivity. The diagnosis of this syndrome should not be made with finality when these symptoms are only of comparatively recent origin. Nonlocalizing (soft) neurological signs, learning disability, and abnormal EEG may or may not be present, and a diagnosis of central nervous system dysfunction may or may not be warranted.

Special Diagnostic Considerations

Specific etiology of this syndrome is unknown, and there is no single diagnostic test. Adequate diagnosis requires the use not only of medical but of special psychological, educational, and social resources.

Characteristics commonly reported include: chronic history of short attention span, distractibility, emotional lability, impulsivity, and moderate-to-severe hyperactivity; minor neurological signs and abnormal EEG. Learning may or may not be impaired. The diagnosis must be based upon a complete history and evaluation of the child and not solely on the presence of one or more of these characteristics.

Drug treatment is not indicated for all children with this syndrome. Stimulants are not intended for use in the child who exhibits symptoms secondary to environmental factors and/or primary psychiatric disorders, including psychosis. Appropriate educational placement is essential and psychosocial intervention is generally necessary. When remedial measures alone are insufficient, the decision to prescribe stimulant medication will depend upon the physician's assessment of the chronicity and severity of the child's symptoms.

CONTRAINDICATIONS

Marked anxiety, tension, and agitation are contraindications to Ritalin, since the drug may aggravate these symptoms. Ritalin is contraindicated also in patients known to be hypersensitive to the drug and in patients with glaucoma.

WARNINGS

Ritalin should not be used in children under six years, since safety and efficacy in this age group have not been established.

Sufficient data on safety and efficacy of long-term use of Ritalin in children are not yet available. Although a causal relationship has not been established, suppression of growth (*ie*, weight gain, and/or height) has been reported with the long-term use of stimulants in children. Therefore, patients requiring long-term therapy should be carefully monitored.

Ritalin should not be used for severe depression of either exogenous or endogenous origin. Clinical experience suggests that in psychotic children, administration of Ritalin may exacerbate symptoms of behavior disturbance and thought disorder.

Ritalin should not be used for the prevention or treatment of normal fatigue states.

There is some clinical evidence that Ritalin may lower the convulsive threshold in patients with prior history of seizures, with prior EEG abnormalities in absence of seizures, and, very rarely, in absence of history of seizures and no prior EEG evidence of seizures. Safe concomitant use of anticonvulsants and Ritalin has not been established. In the presence of seizures, the drug should be discontinued.

Use cautiously in patients with hypertension. Blood pressure should be monitored at appropriate intervals in all patients taking Ritalin, especially those with hypertension.

Symptoms of visual disturbances have been encountered in rare cases. Difficulties with accommodation and blurring of vision have been reported.

Drug Interactions

Ritalin may decrease the hypotensive effect of guanethidine. Use cautiously with pressor agents and MAO inhibitors.

Human pharmacologic studies have shown that Ritalin may inhibit the metabolism of coumarin anticoagulants, anticonvulsants (phenobarbital, diphenylhydantoin, primidone), phenylbutazone, and tricyclic antidepressants (imipramine, desipramine). Downward dosage adjustments of these drugs may be required when given concomitantly with Ritalin.

Usage in Pregnancy

Adequate animal reproduction studies to establish safe use of Ritalin during pregnancy have not been conducted. Therefore, until more information is available, Ritalin should not be prescribed for women of childbearing age unless, in the opinion of the physician, the potential benefits outweigh the possible risks.

Drug Dependence

Ritalin should be given cautiously to emotionally unstable patients, such as those with a history of drug dependence or alcoholism, because such patients may increase dosage on their own initiative.

Chronically abusive use can lead to marked tolerance and psychic dependence with varying degrees of abnormal behavior. Frank psychotic episodes can occur, especially with parenteral abuse. Careful supervision is required during drug withdrawal, since severe depression as well as the effects of chronic overactivity can be unmasked. Long-term follow-up may be required because of the patient's basic personality disturbances.

PRECAUTIONS

Patients with an element of agitation may react adversely; discontinue therapy if necessary.

Periodic CBC, differential, and platelet counts are advised during prolonged therapy.

Drug treatment is not indicated in all cases of this behavioral syndrome and should be considered only in light of the complete history and evaluation of the child. The decision to prescribe Ritalin should depend on the physician's assessment of the chronicity and severity of the child's symptoms and their appropriateness for his/her age. Prescription should not depend solely on the presence of one or more of the behavioral characteristics.

When these symptoms are associated with acute stress reactions, treatment with Ritalin is usually not indicated.

Long-term effects of Ritalin in children have not been well established.

The Ritalin tablets (5 and 20 mg) contain FD&C Yellow No. 5 (tartrazine) which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals. Although the overall incidence of FD&C Yellow No. 5 (tartrazine) sensitivity in the general population is low, it is frequently seen in patients who also have aspirin hypersensitivity.

ADVERSE REACTIONS

Nervousness and insomnia are the most common adverse reactions but are usually controlled by reducing dosage and omitting the drug in the afternoon or evening. Other reactions include hypersensitivity (including skin rash, urticaria, fever, arthralgia, exfoliative dermatitis, erythema multiforme with histopathological findings of necrotizing vasculitis, and thrombocytopenic purpura); anorexia; nausea; dizziness; palpitations; headache; dyskinesia; drowsiness; blood pressure and pulse changes, both up and down; tachycardia; angina; cardiac arrhythmia; abdominal pain; weight loss during prolonged therapy. Toxic psychosis has been reported. Although a definite causal relationship has not been established, the following have been reported in patients taking this drug: leukopenia and/or anemia; a few instances of scalp hair loss.

In children, loss of appetite, abdominal pain, weight loss during prolonged therapy, insomnia, and tachycardia may occur more frequently; however, any of the other adverse reactions listed above may also occur.

DOSAGE AND ADMINISTRATION

Children (6 years and over)

Start with small doses (*eg*, 5 mg before breakfast and lunch) with gradual increments of 5 to 10 mg weekly. Daily dosage above 60 mg is not recommended. If improvement is not observed after appropriate dosage adjustment over a one-month period, the drug should be discontinued.

If paradoxical aggravation of symptoms or other adverse effects occur, reduce dosage, or, if necessary, discontinue the drug.

Where possible, drug administration should be interrupted occasionally to determine if there is a recurrence of behavioral symptoms sufficient to require continued therapy. Improvement may be sustained when the drug is either temporarily or permanently discontinued.

Drug treatment should not and need not be indefinite and usually may be discontinued after puberty.

HOW SUPPLIED

Tablets, 20 mg (peach, scored); bottles of 100 and 1000.

Tablets, 10 mg (pale green, scored); bottles of 100, 500, 1000 and Accu-Pak® blister units of 100.

Tablets, 5 mg (pale yellow); bottles of 100, 500 and 1000.

Dispense in tight, light-resistant container (USP).

665382 C80-14 (1/80)

Consult complete product literature before prescribing

Necrotizing Enterocolitis and Enteral Feeding

Is Too Much Just Too Much?

Ever since Berdon et al[1] and Mizrahi et al[2] characterized neonatal necrotizing enterocolitis (NEC) as a distinct clinical entity, pediatricians have been searching for a unified concept of pathogenesis. Recent reports have attempted to synthesize the multiple factors associated with NEC and have proposed that the critical underlying pathogenic mechanism is either a defect in the integrity of the intestinal mucosal barrier[3] or a primary infectious process.[4]

Goldman, in this issue of the JOURNAL (see p 553), refocuses our attention on the role of enteral feeding and more specifically "overfeeding." In a 13-year review of the experience of one large neonatal unit, he noted that 25 of 26 cases of NEC developed in the three-year period when large feeding volumes (> 150 mL/kg/day) or large daily increases in volume (> 60 mL/kg/day) were the standard practice. When the nursery routine was changed back to limited volumes and restricted daily increments, the incidence of NEC diminished. The concept that enteral feeding may be the primary etiologic factor in the development of NEC has been even more vigorously proposed by Brown and Sweet,[5] who have reported that an extremely restricted feeding schedule has led to all but the disappearance of NEC from their institution.

While Goldman's retrospective epidemiological analysis is of interest, it suffers from all too many of the faults of such studies, namely, poor selection of controls, comparison of nonconcurrent alternative forms of therapy, and reliance on chart data not specifically collected for the study. Of even greater fault is the author's failure to resist the temptation of attributing the development of NEC to a single cause. The most probable pathogenesis of NEC is a complex interrelationship of a triad of factors: disturbed intestinal mucosal integrity, the presence of a critical type and number of bacteria, and a substrate to promote bacterial growth.

A disturbance of the intestinal mucosal barrier appears to be the primary factor in most cases of NEC.[3] This disturbance may be caused by ischemic or hypoxic injury on the basis of vascular insufficiency of the bowel,[2] direct mucosal injury by hyperosmotic feedings,[6] or basic inadequate immunocompetence such as occurs in preterm infants[3] or those deprived of fresh human milk.[4] Lacking an intact mucosal barrier, such a bowel is vulnerable to secondary bacterial invasion. Additionally, as Lifshitz et al[7] have shown, ischemic or hypoxic mucosal bowel injury can predispose to NEC by decreasing mucosal sodium potassium adenosine triphosphatase (ATPase) activity and glucose-galactose transport. The subsequent reduction in carbohydrate transport in the small intestine leads to an increased substrate availability that supports bacterial overgrowth in both the large and small bowel.

Engel[8] has described an NEC-like syndrome in newborn piglets that is accompanied by bacterial invasion of the bowel wall. Histologic data from human tissue usually show similar bacterial invasion.[9] Further evidence of the role of bacteria in the pathogenesis of NEC is that pneumatosis intestinalis or intramural air, the radiologic hallmark of NEC, consists mainly of hydrogen gas, which is derived *only* from bacterial fermentation.[8] In turn, the bacteria that produce hydrogen gas (and that have been associated with NEC) such as *Escherichia coli*, *Klebsiella*, and *Clostridia* sp do so only when presented with a carbohydrate substrate.[8]

Thus, while it is fair to say that feeding appears to be a necessary precondition for bacterial fermentation, hydrogen gas production, and the development of pneumatosis intestinalis, it should be emphasized that pneumatosis intestinalis is only a marker of a phase of the disease process. Furthermore, individual cases of NEC have been reported without evidence of pneumatosis intestinalis.[10-12] What is yet to be proven is that overfeeding itself is the critical variable in the initiation of the necrotizing enterocolitic disease process. Theoretically, overfeeding might support bacterial overgrowth by overwhelming the marginal carbohydrate digestive and absorptive capacity of the immature small bowel and, thus, present substrate for the omnipresent *E coli* and *Clostridia* organisms that colonize the intestine of most neonates within the first 24 hours of age.[4]

Available reported information, however, argues against such a role for overfeeding, despite Goldman's cavalier attempts to dismiss such data. First, although clinical reviews note that over 95% of the infants in whom NEC develops have been fed, there are still reports of NEC developing in the absence of enteral intake.[5,12] Second, in the only controlled study published to date, Book et al[13] showed that two modest rates of increases (10 mL/kg/day vs 20 mL/

kg/day) and a modest maximum of 140 mL/kg/day at 14 and 7 days of age, respectively, did not result either in differences in the incidence of NEC or in the eradication of NEC. Third, recent reports of clustered, epidemic-like cases[4,14] have included infants up to 1 month of age without the classical risk factors previously associated with NEC. These clustered cases emphasize an infectious-type etiology and not a feeding-related etiology. If overfeeding is the primary factor in the development of NEC through its enhancement of bacterial growth and fermentation and hydrogen gas production, one would expect that the radiologic evidence of such, ie, pneumatosis intestinalis, would correlate with the severity and course of the disease process. However, the opposite is all too often the case.[12,15] In fact, as noted, the enterocolitic-necrotic aspect of the disease may occur without any pneumatosis intestinalis.[10-12]

A recent epidemic in our institution illustrates the difficulties in attributing NEC to a particular feeding regimen. Necrotizing enterocolitis developed over a ten-day period in five infants, three of whom were between 17 and 30 days of age. None of the infants had experienced perinatal asphyxia and three had no respiratory distress or indwelling umbilical catheters. Two had only very mild respiratory distress requiring supplemental oxygen and umbilical catheter placement for less than 48 hours. All infants were fed with fresh breast milk or isotonic commercial formulae in amounts not exceeding 150 mL/kg/day. In addition, large daily increases in feedings (> 50 mL/kg/day) did not occur. All these infants were seen initially with severe pneumatosis intestinalis together with portal venous air at least a week after resolution of all respiratory symptoms and institution of feedings. Four of five infants survived without sequelae and one died.

Our experience, as well as other now well-described cluster-like epidemics,[4,14] illustrate the danger in concluding, as Goldman and Brown and Sweet[5] have, that a single change in feeding practice will eradicate or significantly decrease either the incidence or the morbidity and mortality from NEC. Additionally, an overemphasis on the role of enteral feeding and the development of NEC poses the question as to what are the alternatives. Brown and Sweet's[5] recommendations limit caloric intake to levels that are marginal for adequate growth in many growing preterm infants. If their protocol is followed, the inevitable conclusion is that parenteral nutrition with all its known and unknown hazards must be used. If one takes the position that *no* enteral intake should be given in the first week or two of life, when NEC is most common, then one mandates total parenteral nutrition for all such infants with no assurance that NEC will not develop when enteral intake is finally started.

An alternative to restriction of enteral feeding in all preterm infants might be to select, on a clinical epidemiological basis, a particular high-risk group for the development of NEC and restrict their enteral intake. However, there are two problems with this approach. For one, matched studies indicate that the supposed "risk factors" such as low Apgar scores, hypothermia, respiratory distress, hypotension, umbilical catheter placement, or exchange transfusions are not predictive of the development of NEC.[12] In addition, other studies indicate that in 10% to 20% of infants in whom NEC does develop no such "risk factors" were present.[4,16]

What, then, are the options for the clinician? Until more data are available one should not follow Brown and Sweet's[5] dictum and obligate the high-risk preterm infant to limited enteral feeding at a time of possible critical brain growth or subject him inevitably to the risks of parenteral nutrition. On the other hand, one should pay heed to Goldman's experience and limit the enteral intake to reasonable daily quantities and daily rates of increase. Furthermore, in view of the data of Lifshitz et al,[7] when there is the strong possibility of bowel ischemia secondary to prolonged hypotension, presence of a clinically significant patent ductus arteriosus, and/or moderate to severe perinatal asphyxia, enteral feeding should be cautiously introduced, preferably with fresh human breast milk or alternatively with isotonic commercially available formulae. This approach might well reduce the incidence and severity of NEC. Unfortunately, the epidemic-like clusters of cases wherein a particular infectious agent is the primary cause will, regrettably, continue to strike the vulnerable neonate.

The Cardiomyopathy of Hypothyroidism Revisited

Are Children Different Than Adults?

Amidst the wide range of social, political, and scientific developments that are presently capturing our attention, the year 1980 will quietly mark the centennial anniversary of the first report of gross anatomical findings in the heart of patients with myxedema by Sir William Ord.[1] The celebration of this event would hardly receive notice in a modern medical journal were it not for a remarkable resurgence of interest in the study of the heart as a target organ for thyroid hormone action. This welcomed new trend results from the creative application of seemingly unrelated advances in the disciplines of endocrinology and cardiology. By combining radioimmunoassay techniques for measurement of thyroid function with the versatility of echocardiography and systolic time intervals as noninvasive tools for the assessment of functional and structural cardiac alterations, investigators are rapidly adding to our understanding of hypothyroid heart disease. The study by Hayford et al in this issue (page 556) is, to our knowledge, the first to apply these techniques to the pediatric age group.

Contrasting with this new trend, the acquisition of knowledge concerning the consequences of thyroid hormone deprivation on the cardiovascular system over the past century was characterized by a relatively slow and controversial pace. The classic "Report of a Committee of the Clinical Society of London nominated December 14, 1883, to Investigate the Subject of Myxeodema"[2] describes the hearts of nine patients dying with myxedema, and the heart was considered abnormal in two patients. In subsequent necropsy studies, the hypothyroid heart has been variously described as pale or "flabby," with normal or dilated chambers, and with or without ventricular hypertrophy. As would be expected, autopsy reports of hypothyroid heart disease have virtually disappeared from the literature in the past two decades.

In 1918, Zondek[3] first suggested that myxedema could lead to disturbances in cardiac function. His concept of "myxedema heart" was subsequently supported by the careful clinical observations of Fahr.[4] For many years thereafter, the findings of enlargement of the roentgenographic cardiac silhouette, slow indolent heart action on fluoroscopy, low voltage of the QRS-complex, flat T waves on the ECG, and distant heart sounds were considered highly indicative of hypothyroid heart disease. Because some of these clinical features were subsequently found to result from pericardial effusions,[5] which frequently accumulates in untreated myxedema, controversy again arose concerning the existence of a true cardiomyopathy in this disorder.

Since the late 1950s, an increasing body of clinical and experimental evidence has gradually accumulated that consistently points toward functional and structural alterations of the heart muscle in untreated hypothyroidism. Low cardiac output, reduced stroke volume, and depressed contractility have been demonstrated by hemodynamic methods in hypothyroid patients.[6,7] Using the technique of systolic time intervals, several investigators studying adult hypothyroid patients documented reduction of the left ventricular ejection time (LVET) and prolongation of the preejection period (PEP).[8,9] These measurements are indirect indices of decreased myocardial contractility and in all reported series were reversed by thyroid hormone replacement. A previously unrecognized echocardiographic pattern of asymmetric thickening or hypertrophy of the interventricular septum, reduced left ventricular internal dimensions, reduced left ventricular outflow tract dimensions, reduced systolic septal excursions, and occasional systolic anterior motion of the mitral valve have been reported in a study of adult hypothyroid patients recently completed at our institution.[10] These echocardiographic features, which at times can completely mimic the pattern of a hypertrophic obstructive cardiomyopathy, were also reversed after thyroid hormone treatment. This unusual finding of a hypertrophic cardiomyopathy in hypothyroidism has been substantiated by autopsy examination of the hearts of three patients dying with uncorrected hypothyroidism.[11]

Within this framework of past controversy and rejuvenated inquiry, the communication by Hayford et al is of importance. To our knowledge, it is the first systematic investigation of the effects of hypothyroidism on the hearts of the young, and these investigators failed to demonstrate significant cardiac impairment in their pediatric patients. The puzzling feature of their study is that the data and conclusions, although derived by similar methodological approaches, are in direct variance with the evidence recently gathered in hypothyroid adults.[8,9] This facet of their article serves clearly to underscore the need for restraint in attempts to extend information obtained in studies of adults to a pediatric population. In the specific case of hypothyroidism, the clinical manifestations of the same pathological process vary widely among different age groups.

RECOGNIZING HYPOTHYROIDISM

In adults, the development of signs and symptoms of hypothyroidism follows a lengthy and insidious course,

with the diagnosis remaining unsuspected for long periods of time. In the elderly, the recognition of hypothyroidism may be masked by neuropsychiatric symptoms that suggest senile dementia, psychosis, or chronic brain syndrome. The ability to date the onset of hypothyroidism in the adult can be accomplished by questioning the patient after full thyroid replacement. In our study of 22 hypothyroid individuals, most patients indicated that their thyroprivic state had been present for four to eight years before diagnosis.[10] One woman, when her condition was fully corrected, insisted hypothyroidism had been present for 16 to 18 years. Hayford et al recognized in their study that dating the onset of hypothyroidism in children is more difficult.

Unlike adults, the diagnosis of hypothyroidism in children is probably made earlier in the course of the disease. Complaints from parents and teachers who compare the affected child with normal siblings or peers alert the physician of the possibility of juvenile hypothyroidism. The physical findings of growth retardation, infantile appearance, and failure in the development of secondary sexual characteristics serve as additional clues to an early diagnosis.

In this context, we would recommend caution in interpreting the data of Hayford et al as an absolute negation of the existence of a cardiomyopathy in untreated hypothyroid children. We perceive their report as additional support to the concept that most of the cardiac consequences of hypothyroidism result not from the severity of thyroid hormone deficiency as reflected by serum concentrations of T_4 and thyroid-stimulating hormone, but from the duration of years in the hypothyroid state. This concept, first proposed by Farh in 1932[12] was clearly substantiated in our adult echocardiographic study aforementioned. In our experience, the severity of cardiac involvement as reflected by the degree of asymmetric thickening of the interventricular septum and compromise of cardiac function correlated better with the duration of the thyroprivic state as assessed by historical documentation, rather than with the degree of hypothyroidism or the absolute values of the thyroid function tests.

CARDIAC FUNCTION

Despite the negative findings presented by Hayford and his colleagues, we believe that abnormalities in cardiac function assessed by systolic time intervals or structural changes detected by echocardiography in the pediatric age group will probably be noted in future studies of older hypothyroid children, if the duration of the thyroprivic state is sufficiently long. It is interesting to note that in Hayford's series the PEP and the PEP/LVET ratio of patient 14, (a 15-year-old) were well above the upper limits of normal for the stated age prior to treatment and clearly returned to normal following thyroid replacement. Unfortunately, the systolic time intervals could not be determined in four of the seven subjects above age 12 in the series of Hayford et al because of technical problems in the echocardiographic tracings. In our series of hypothyroid individuals examined by echocardiography, the youngest patient was a 16-year-old schoolgirl with a bone age of 12 years. Although her interventricular septum measured 11 mm in thickness (the upper limits of normal for an adult), it was well above 7 mm, the upper limits of normal for her chronological age, body surface area, and bone age. In this child, the septal thickness regressed to a normal width after thyroid replacement. We would recommend that future studies of hypothyroid children take into account not only chronological age but also their body surface and, if feasible, their bone age. The latter determination, as well as growth curves, should allow determination of the length of the thyroprivic state.

Mounting experimental evidence points to the heart as being a target organ for thyroid hormone.[13,14] The metabolic derangements caused by thyroid hormone deprivation leading to functional and structural abnormalities demonstrated in adult patients are unknown. The defect may represent a biochemical lesion leading directly to decreased muscle contractility. Alternatively, the accumulation of mucopolysaccharides that has been demonstrated in adult human pathological material,[15] and in experimental animals,[16] may lead to an infiltrative or hypertrophic cardiomyopathy. It is probable that both types of processes are operative in long standing hypothyroidism. Thyroid is not the only hormone to affect the heart. Perturbations in growth hormone[17] and insulin[18] have been shown to lead to a hypertrophic cardiomyopathy in adults and infants, respectively.

Independent of these speculations, the article by Hayford and co-workers wisely emphasizes a frequently forgotten clinical fact. The enlargement of the cardiac silhouette commonly seen in hypothyroidism does not reflect a dilation of the chambers due to a failing myxedematous myocardium, but rather results from the accumulation of pericardial effusion. We agree with their conclusions that simple enlargement of the roentgenographic cardiac silhouette unaccompanied by clinical or echocardiographic signs of cardiac dysfunction should not constitute a deterrent to rapid and appropriate thyroid hormone replacement.

Regression and Clinical Research

The term *regression* ordinarily suggests some kind of personality or behavior dissolution, when used by physicians or other clinically oriented professionals. A different kind of regression occurs when the clinical geneticist discovers that the sons of tall fathers are not quite as tall, on the average, as their fathers. The sons of short fathers also "regress" toward the population mean, ie, on the average the sons are closer to the mean height of the population than are their fathers. The word "regression" does not have only the behavioral meaning of coming apart or backsliding; it may also mean "recentering" or "reaveraging" in certain interesting clinical situations.

To the statistician, regression may mean several different things. These multiple meanings can confuse the nonstatistician clinician. At least five concepts or associations have an aspect that relates to regression: (1) the *regression line*, depicting the relationship of two variables observed from each element of a sample; (2) the calculations concerned with multiple variables from each element of the sample, often called *multiple regression*; (3) the *filial regression* of characteristics across generations; (4) a form of *regression with correlation*: examination of one set of variables from a sample may show a regression in a correlated set of variables from that sample; and (5) the clustering of repeated sample means around the central value of the population: a *regression of samples* to the universe mean.

A nonmathematical look at each of these forms of regression should help make their occurrence in research reports and in the clinical literature less confusing to nonstatisticians.

REGRESSION LINE

When two measurements on each element of a sample bear a numerical relationship of some systematic sort, the mathematical association may be depicted in a line, called the "regression line." Most researchers are delighted if the line is straight, but statisticians also work with curved or curvilinear regression lines, if such lines best describe the relationship between two variables. Within reasonable boundaries, examples of fairly straight regression lines would be height and arm length, IQ scores and school grades, or hematocrit and hemoglobin measurements.

Several good statistics books[1-4] present the numerical procedures for finding the regression line. Enthusiasm for this kind of regression line exists because it allows the investigator to use one variable to predict another variable. The formulas can tell how accurate such predictions might be, and over what range of values the predictions are valid.

Some statisticians[3] make elaborate distinctions between the regression line, which shows the association between two sets of variables (bivariate regression), and the related concept of correlation of two sets of variables. The regression phenomenon can be expressed in a formula; and, if a line exists for the association of variables, the line can be drawn on a surface. It is often called the "line of best fit."[3] Correlation is a more mathematical concept, tending to show the "tightness of fit" of variables that are more or less correlated with each other.

One author[3] advises that correlation should be used to describe the relationship between variables not under the investigators' control. For example, a correlation might be found between cigarette smoking and lung cancer, both these variables being outside the control of the investigator.

Regression lines, on the other hand, might be used when the investigator can control one of the variables (the independent variable) so as to predict the consequent variable (the dependent variable). An example might be the investigation of pulse rate in response to running at various speeds, controlled by the investigator. A nonbiologic example might be the regression line of caffeine concentration in coffee brewed for various lengths of time.

MULTIPLE REGRESSION

When several variables on each member or element of a sample have a numerical relationship of some systematic sort, the mathematical links may be called "multiple regression" or "multivariate."[1,5] The relationships cannot be shown in a line of two dimensions, because the relationship becomes one of multiple dimensions.[1,5,6] In general, multiple regression techniques have been more widely accepted among researchers in psychology, education, and social sciences, than among those in biology or medicine.

Some authorities in medical research view analysis of multiple variables with considerable skepticism. Feinstein[6] wrote, "Every investigator I have met who uses these techniques either does not fully comprehend the complicated mathematics or has been unable to provide a succinct explanation."

Even in the face of his skepticism, Feinstein gave an interesting example of how analysis of multiple variables might be useful in clinical problems. The development of coronary artery disease (the target variable) might vary in relation to baseline (independent) variables like sex, age, weight, smoking habits, blood pressure, and serum lipid levels. Each of these variables might contribute to a regression line "predicting" coronary artery disease. The line could not be drawn in two-dimensional space, but it could be represented mathematically.

FILIAL REGRESSION

A pioneer in psychological research, Sir Francis Galton, described "filial regression to the mean."[7] This is the drift of offspring toward a general population mean when their parents are known to fall in an extreme tail of a bell-shaped curve. Sons of tall fathers, on average, are nearer the mean height of the general population than their fathers were. Normal parents, from the low tail of the population for IQ, have children with IQ scores that average slightly higher than those of the parents, ie, the children's scores "regress" toward the general IQ mean. This intergenerational kind of regression is sometimes confused with a within-generation "regression" from one attribute to another, as discussed in the next section.

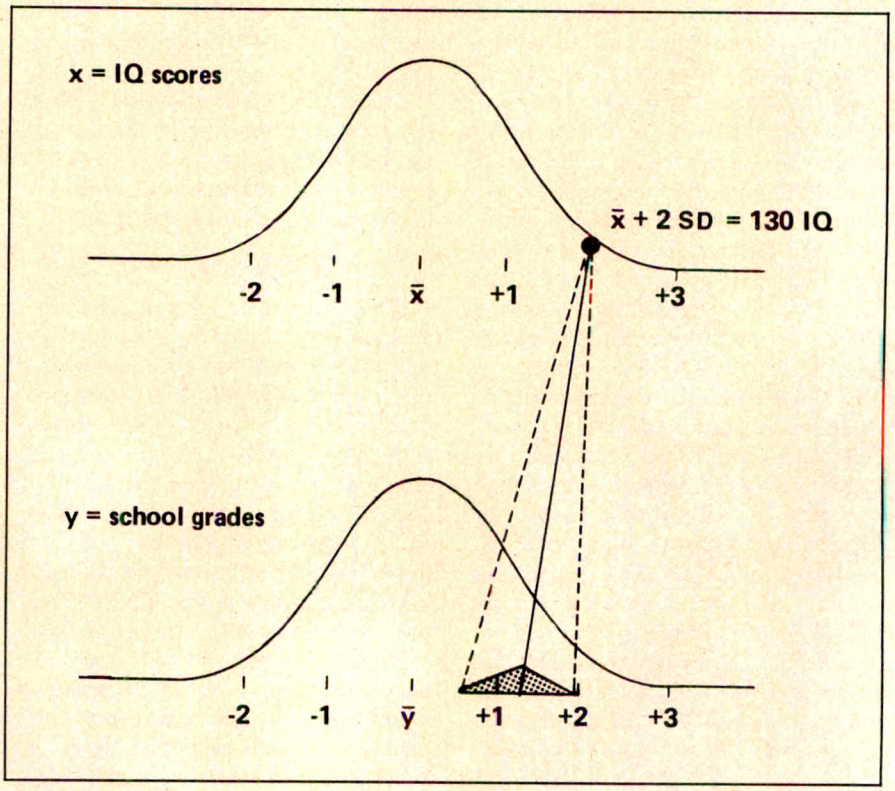
REGRESSION WITH CORRELATION

The filial regression is across generations. It must be distinguished from a different kind of statistical regression across correlated variates from elements of a sample. Let us say, since it is true, that IQ scores are highly correlated with academic grades. If the correlation is high and the calculations are accurate, the educator may find a reasonable estimate of academic potential from IQ scores.

Let us take a look at a subsample of students with IQ scores of 125 to 135 (which would put them about 2 SD above the general population mean IQ of 100). If one looks at the grade point scores for these high-IQ students, these will be, on average, nearer to the population average grade score than their IQ scores are to IQ average; that is, the grade scores may be said to "regress" toward the mean for grades. This relationship is shown in Fig 1. This regression can occur in situations where two measurements of each subject are correlated in a statistical sense. The mathematics of this regression are presented in textbooks of statistics,[5,8,9] although the nonstatistical clinician may be dismayed by the symbolic notations.

The *magnitude* of this kind of regression from one set of variables (IQ) to the other set (school grades) will depend on the results of three calculations: (1) the correlation coeffi-

When two sets of measurements from each element of sample are correlated, subset taken from either tail for one variable will seem to "regress" toward the mean of correlated variable. Magnitude of regression will depend on level of correlation and variance (dispersion) of each set of measurements.[9]



cient between the two sets of measurements; (2) the variance (dispersion, variation) estimated for one variate; and (3) the variance estimated for the correlated variate. For the mathematically comfortable, the formulas and interpretations are presented by Blalock.[1]

CENTRAL TENDENCY REGRESSION

A statistical phenomenon has, in clinical literature,[10] been called "regression to the mean." A few words about sampling theory might clarify this interesting phenomenon.

Samples of large populations (universes) are taken with the expectation that the sample characteristics (called statistics) will provide fair estimates of the universe's characteristics (called parameters). A statistical law says the more clean samples taken from a population, the better the estimates about the dimensions of the universe of interest. (The universe is too large to examine, or one would measure its parameters directly.)

The more samples well studied, and the larger each is, the better the source population can be characterized and its numerical dimensions estimated. As more and more sample averages are determined, the more these averages will cluster, centralize, or regress around the mean of the (impossible to measure) population. In fact, even if the source population (say, weight) is not distributed in a bell-shaped, Gaussian curve (which weights are not), the *averages* of samples will tend to array themselves in a bell-shaped fashion, and the *average of the averages* will be a good estimate of the population mean, becoming better as more samples are averaged.

Where does regression come in? Let us say that a researcher, aware or unaware, selects a sample from either extreme tail of a bell-shaped distribution, then finds the average of that sample. If he takes another sample from that universe, the second sample will likely be found to regress toward the population mean. Even inanimate objects will follow this pattern. If one throws 1,000 dice once, about one in six will turn up with the ace showing; the average score for this subgroup of dice is "1." If those dice that showed the ace are thrown again (a second sample from a universe of dice), they are unlikely to show all aces again; instead, the average score will be some value near the mean score of 3.5. The second sample score has regressed toward the population mean. If one throws samples of dice repeatedly, or even just one die, the averages for each throw (sample) will inexorably centralize (cluster, regress) around the universe mean for dice, or what the statisticians call a *central tendency.*

Some writers make these concepts more obscure than they need to be. For example, McGuigan,[2] in his excellent textbook on research in psychology, wrote, "The regression effect is a statistical artifact that occurs in repeated testings such that the value of the second test score regresses toward the mean of the population."

The tendency of sample means to have a central tendency is not really an artifact; it is a numerical reality of sampling. McGuigan says "repeated testings" when the event is really "repeated sampling." This is a crucial difference, because repeated testing of the same sample will give you results very close to the first testing, with only the random errors of the method causing a change.

One final point should be considered. Even if the first testing is out in an extreme tail of a distribution, there is no absolute assurance that the second sample *must* show a value closer to the population mean; in rare instances the second sample will move even farther out into the tail. It would be more accurate to say that all subsequent samples would have a tendency to cluster around the population mean. If the first sample was from an extreme tail, then the subsequent samples might be said to "regress to the mean" or to show a "regression effect."

As with many situations in clinical research, there are practical aspects that muddy the crystal clarity of numbers. The "central tendency" of multiple samples assumes that the samples are drawn from a relatively homogeneous universe. It would not be appropriate, for example, to lump samples of caffeine measurements from ordinary coffee with caffeine measurements from decaffeinated coffee, just because both universes can be called "coffee." The low caffeine levels in the decaffeinated coffee would not be merely samples from the low tail of a big coffee curve.

This mixing of populations occurs when biology clutters up pure measurement variation. The pattern of laboratory measurements of a substance, say cholesterol, measured repeatedly from a single blood specimen will show a central tendency and a random variation around the central value, depending on the reliability (reproducibility) of the method. In addition, many laboratory procedures contain a second source of error variation, a calibration or standardization error that is nonrandom and may be more in one direction than another. This kind of error may occur when the technician unconsciously favors rounding off instrument readings to the next highest even number; or prefers numbers ending in zero or five over other numbers. (Has any physician ever seen a blood pressure measurement ending in an odd number?)

The random and nonrandom variations due to laboratory techniques are likely to be small in comparison with variation imposed by biology. Accurate measurements of height of the same person will change from morning to night. Body temperatures, hydration, and biochemistry variations change from hour to hour, even in the same person. Add to this the across-individual variations, and the total variance grows apace, even with the best science.

Measuring caffeine in aliquots of coffee from a single cold pot is not the same sampling procedure as measuring caffeine from different pots, some mild, some strong, and some decaffeinated. Each pot will have its own mean, toward which aliquots from that pot will tend to drift.

One challenge to researchers is to distribution. If so, then repeated samples would be expected to tend toward a central value. On the other hand, the sample may look like it is from an extreme tail, but is actually from a separate universe. The serum bilirubin levels of 2-day-old infants are not

simply high tail values from a Gaussian curve of infant bilirubin levels; they are a universe of their own. An IQ of 80 in a child with Down's syndrome is a high tail value for the Down's universe, not a low tail value for normal childhood IQ.

It is risky, as Laskarzewski et al[10] did, to assume that serum lipid measurements for children aged 7 to 14 years are part of the same statistical universe as samples from these children taken four years later, even if the children are called the "same subjects." This assumes that serum lipid values are homogeneous over a broad range of early childhood. The universe of childhood lipid levels may be quite different in its parameters than the universe of adolescent lipid values, even when the same persons are used as subjects.

This is the kind of risk that one takes in concluding that a diastolic blood pressure of 85 mm Hg in a 13-year-old boy is a sample from the high tail of the normotensive universe of youth. In biologic reality, the boy may be in the low tail of a curve from a different universe, one called "hypertensive youth." If the boy is from the normotensive universe, repeated samples of his blood pressure will act as samples from a population with a central tendency much below 85 mm Hg diastolic. His blood pressure will seem to regress toward normal, for in fact the measurements are repeated samples from a normal population. On the other hand, if he is a member of the universe called hypertensive, repeated samples of his blood pressure will cluster to the mean for that population, perhaps around 95 to 100 mm Hg diastolic.

This biologic uncertainty about whether a sample is from an extreme tail of a distribution dictates the use of control groups. By using controls, the possibility of regression to some unknown mean (central tendency) is evenly balanced across the treated and the untreated. This allows the effect of treatment or intervention to be distinguished from the tendency for samples to drift toward their population mean.

Biology does another ugly thing to some sample measurements: it allows some measurements to vary in one direction but not in the other. Children can grow taller, but not shorter. We rarely see body temperatures 3 °C below 37 °C, but we often see temperatures 3 °C above normal. Blood glucose levels can only fall about 100 mg/dL below normal, but they can rise several multiples of that above normal.

Schor[11] wrote that all the flies in a closed room might be on the ceiling at 8 AM; but at some point in the following 24-hour period, more of them would be below the ceiling than above it. This nicely portrays the difference between biology and pure random variables. In biology, the room may be closed and the flies restricted to staying on the ceiling or below it. In a random universe, the flies would be allowed random movement; so that at some subsequent time, there could be just as many flies above the ceiling as below it. Schor's parable reminds us to be on guard about the purity of unencumbered numbers (remember those dice), in contrast with the sometimes muddy and perverse variables of biological and other dynamic systems.

McGuigan[2] points out an interesting variant on the central tendency (regression) phenomenon. He discusses the "interrupted time series." An observer may select the highest recent value of a time sequence of values as a baseline, rather than finding the true baseline over the entire series. Selecting a recent extreme value makes it likely that the next point on the time sequence curve will be closer to the baseline of the entire sequence. McGuigan used the example of highway traffic deaths. The researcher chose the latest and highest value in a time sequence curve for traffic death rates, then attributed a subsequent fall in the death rates to the intervention of a traffic safety program. Rainfall measurements are likely to drift toward the average rainfall, after a record high rainfall. Beware of data in a time series that follow closely after a series high or a trough.

Feeding and Necrotizing Enterocolitis

Herbert I. Goldman, MD

• **Twenty-six infants had necrotizing enterocolitis (NEC) in the neonatal unit of the Long Island Jewish-Hillside Medical Center, New Hyde Park, NY, between 1964 and 1976; 25 of these cases occurred between 1973 and 1976. The relationship of feeding practices to this clustering of NEC cases was investigated in two ways: (1) A 10% sample of all admissions, 1964 to 1976, was studied. A striking correlation was found between the yearly incidence of NEC and the percentage of infants in that year who had received large increases in daily feeding volume. The highest mean daily feeding volume occurred in 1974 and 1975, the two years of peak NEC incidence. (2) The feeding records of the 26 NEC cases were studied. Thirteen NEC patients had had large increases in feeding volume within two days of NEC onset. Seven others received > 150 mL of formula per kilogram per day prior to NEC onset. Rapid increase in feeding volume and the use of large volumes are suggested as important etiologic factors of NEC.**

(*Am J Dis Child* 134:553-555, 1980)

Necrotizing enterocolitis (NEC) was virtually unknown in the neonatal unit of the Long Island Jewish-Hillside Medical Center (LIJHMC) during the 1960s and early 1970s. In the mid 1970s, concurrent with a change in feeding policy, the incidence of NEC increased dramatically. The present study was designed as an epidemiologic investigation of the relationship between feeding practices and NEC in the neonatal unit of our hospital.

MATERIALS AND METHODS

The study consists of three parts: (1) determination of the incidence of NEC during the period from 1964 to 1976; (2) determination of the feeding practices and their variation during this time period; and (3) determination of the feeding practices in the group of infants with NEC.

The study was limited to infants admitted to the neonatal unit between Jan 1, 1964, and Dec 31, 1976. Only infants with birth weights less than 2,500 g were included.

Standardized methods were used for case findings and standardized criteria were adopted for the diagnosis of NEC. Three methods were used for case finding:

1. Face sheet diagnosis: All charts with a face sheet diagnosis of necrotizing enterocolitis, enteritis, or colitis were reviewed. A case was accepted as NEC if there was definite roentgenographic evidence of pneumatosis plus two or more of the following: (*a*) vomiting; (*b*) abdominal distention; and (*c*) grossly bloody or guaiac-positive stools.

2. Deaths: The charts of all infants dying after the second day of life were reviewed. A case was accepted as NEC if an autopsy showed pathological findings of NEC or, if no autopsy was done, the case fulfilled the criteria for face sheet diagnosis.

3. Abdominal surgery: The charts of all infants subjected to abdominal surgery (other than herniorraphy) were reviewed. A case was accepted if there were pathological findings of NEC.

The chart of every tenth admission to the neonatal unit between Jan 1, 1964, and Dec 31, 1976, with birth weight less than 2,500 g was reviewed. The total volume of feeding received by the infant during each 24-hour period was recorded for each of the first 14 days of life. This value was divided by the current weight of the infant to yield the daily feeding volume in mL/kg. Differences between the daily feeding volumes for adjacent days were calculated and recorded as the daily feeding volume increase in mL/kg.

The daily feeding volume and the daily feeding volume increase were calculated and recorded for each infant with NEC on every day of life up until the infant was taken off feedings because of NEC symptomatology. All statistical analyses were carried out by calculation of χ^2 with Yates' correction.

RESULTS

A total of 26 cases of NEC were found. Only one occurred prior to 1973, with the remaining 25 clustered in the period from 1973 to 1976. The increased incidence for 1973 to 1976 is not accounted for by the numbers of admissions or survivors (Fig 1). The percentages of infants less than 1,500 g in birth weight were 29.8 in the years 1964 to 1972 and 27.6 in the years 1973 to 1976. The percentages of infants born elsewhere and transported to the neonatal unit were 54.8 in the 1964 to 1972 period and 61.1 in the 1973 to 1976 period.

The mean daily feeding volumes in the seventh and 14th days of life, based on the 10% sample, are given in Table 1. The highest daily feeding volumes on the seventh day occurred in 1974 and 1975, the two years with the highest incidence of NEC.

The percentage of infants who received one or more large daily feeding volume increases (> 40 or 60 mL/kg/day) is shown in Fig 2. The figure reveals a striking parallelism between the incidence of NEC and large jumps in feeding volume.

The percentage of infants in whom feedings were delayed for more than two days is as follows: 1964 to 1968, 15%; 1969 to 1972, 12%; and 1973 to 1976, 24%. A larger percentage of the infants had delayed feedings during the most recent period (1973 to 1976), possibly reflecting the use of respirators.

The data for feeding volumes in the 26 cases of NEC are given in Table 2. Twenty of the infants (77%) were receiving more than 100 mL/kg/day immediately prior to the onset of NEC. Fifteen of the 26 infants (57%) had received one or more large daily feeding volume increases (> 60 mL/kg/day) prior to the onset of NEC. This proportion is significantly higher than the 15% incidence of such large daily increases in the 13-year period from 1964 to 1976 ($P < .0001$), and it is also significantly higher than the 29% incidence of such large increases during the four-year period from 1973 to 1976 when all but one case of NEC

*NEC indicates necrotizing enterocolitis.

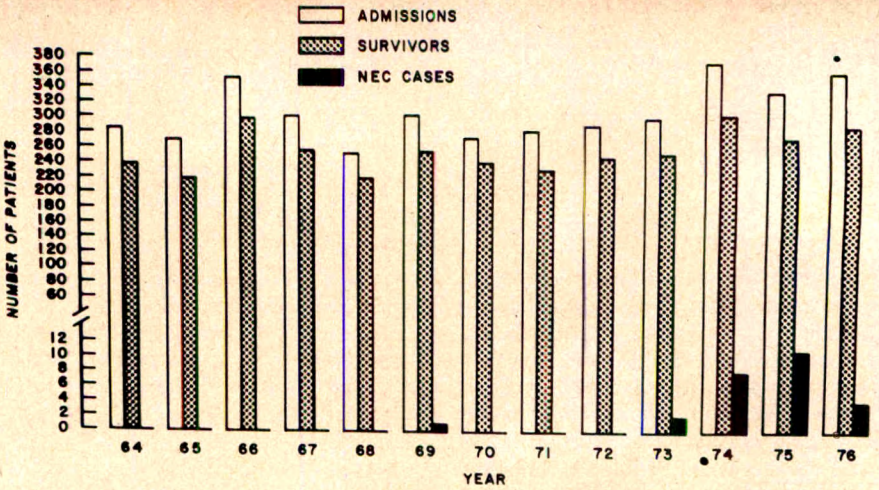

Fig 1.—Numbers of admissions, survivors, and cases of necrotizing enterocolitis (NEC).

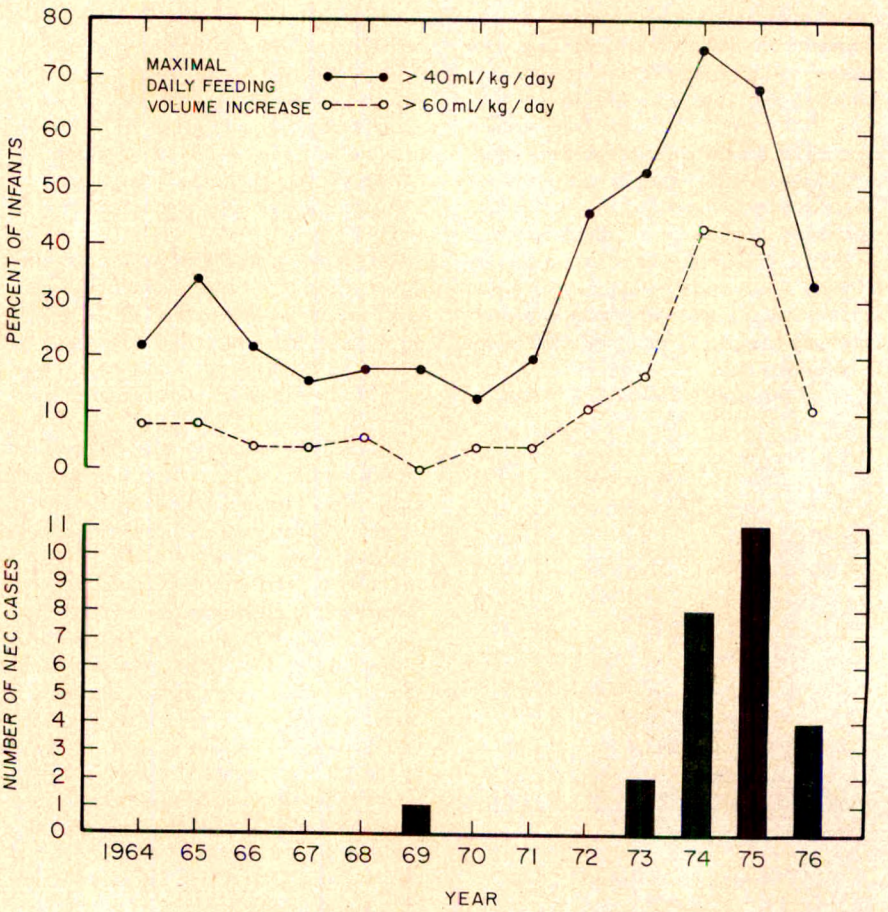

Fig 2.—Percentage of infants with rapid increase in feeding volume.

occurred ($P < .005$). Also, in 13 of the 15 infants who were subjected to one or more large daily feeding volume increases preceding NEC, a large daily increase occurred during the two days prior to the onset of NEC, and in 11 infants, on the day prior to the onset of NEC.

The 26 patients with NEC can be characterized as follows: (1) Thirteen had received large daily feeding volume increases within two days of the onset of NEC. These were large infants (nine > 1,500 g), with early onset of NEC (three to eight days for 11 infants). (2) Seven others were receiving large volumes (> 150 mL/kg/day) prior to the onset of NEC. These were small infants (six < 1,500 g), and all had NEC after seven days. (3) Four infants had had an exchange transfusion within two days of the onset of NEC. This group includes the infant who was never fed. (4) One infant had received a daily feeding volume increase of 55 mL/kg prior to the onset of NEC. (5) The 26th infant had not received a large daily feeding volume increase, a large daily feeding volume, or an exchange transfusion.

Of the 26 cases of NEC, 11 infants (43%) weighed less than 1,500 g at birth. Seventeen (65%) were male. The disease began at 3 to 7 days of age in 15 (54%) and at 8 to 35 days in the remainder. Oxygen therapy had been used for 21 infants (81%), and a respirator for nine (35%). Umbilical artery catheterization had been carried out in 18 babies (69%), and an exchange transfusion in six (23%). Fifteen infants had surgery, and ten of these died; nine of the 11 who were treated medically died. The overall mortality was 73%.

Seven different formulas had been used during this period. Thirteen infants received either Similac 20 or 24 (Ross Laboratories) or Enfamil 20

or 24 (Mead Johnson & Co); nine were given PM 60/40 (Ross Laboratories); three received hyperosmolar feeds (two, Nutramigen [Mead Johnson & Co] and one, Similac 27); and one infant was never fed. Intermittent gavage was used for 21 infants, continuous nasojejunal feedings for three and nipple feedings for one. Gluconate calcium was added to the diet of four infants.

COMMENT

With rare exception, NEC occurs after oral feedings have been given (63 of 64 cases[1]; 54 of 54[2]; 61 of 61[3]; 42 of 43[4]; 21 of 24[5]). In the present study, 25 of 26 infants were being fed at the onset of NEC.

In 1974, Krouskop et al[5] related NEC to overaggressive feeding. They reported that 18 of 24 infants with NEC had symptoms on an average of 31 hours after starting oral feedings (mean formula intake, 72 mL/kg/day). Brown and Sweet[6] later introduced a regimen of slowly progressive feeding to the New York Mount Sinai Hospital Neonatal Unit and then noted a dramatic drop in incidence of NEC, from 14 cases in 3½ years to one case in the subsequent four years.

Book et al[7] described a sharp increase in the incidence of NEC (from 0.3% to 5.1%) concurrent with the introduction of a more rapid increase of feeding volume. A total of 29 babies of birth weight less than 1,200 g were then randomly fed the mean feeding volume of either the "gradual-increase-of-feeding-volume" period or the "rapid-increase-of-feeding-volume" period. Necrotizing enterocolitis developed in three of 15 from the rapid-fed group and in two of 14 from the gradual-fed group, a statistically nonsignificant difference. These results are not persuasive for two reasons: (1) Use of a small sample size may have led to missing important differences.[8] (2) Use of the mean feeding rates in the randomized trial did not replicate the conditions in the naturally occurring gradual- and rapid-feeding periods. The fastest feeding rates at the top of the range of the rapid-feeding period (perhaps the most likely to produce NEC) were eliminated. Conformity to the mean in the gradual-feeding group did not allow for individual variation based on the infant's condition and response to feedings, which might have made NEC less likely in the gradual-feeding period.

Frantz et al[2] carried out a retrospective, case-control study of 54 cases of NEC and 98 weight-matched controls. All 54 cases of NEC were receiving oral feedings prior to the onset of NEC while *only 63% of controls were receiving oral feedings on the same day of life that symptoms developed in the matched NEC patient* ($P < .001$). The infants with NEC had more umbilical and arterial catheters, but they were equally ill as judged by Apgar scores, blood pressures, temperatures, presence of respiratory distress syndrome, and use of respirators. These data are strongly supportive of the hypothesis that feeding practices are of major etiologic importance in NEC.

Historical Perspective

Hess and Lundeen,[9] pioneers in the care of premature infants in the United States, wrote:

> The tendency to overfeed the young premature infant is undoubtedly one of the important factors in the mortality and morbidity found among premature babies during their first 3-6 weeks of life.

They recommended, "feeding very small amounts of food and then increasing the amount very slowly," and they advised not giving more than 100 cal/kg/day until the infant is at least a month old and then described vomiting and abdominal distention as possible consequences of overfeeding. It is worth noting that Hess and Lundeen's[9] recommendations define almost precisely the feeding boundary beyond which most of the infants of the present study had NEC, ie, increasing feeding volumes rapidly or giving more than 100 cal/kg/day (150 mL/kg/day of a 0.66 cal/mL formula) to an infant of birth weight less than 1,500 g within the first month of life (latest day of onset of NEC in our patients was 35 days).

Possible Mechanisms

Hasselmeyer and Hon[10] noted severe bradycardia in healthy premature infants receiving 10 to 45 mL of formula by gavage. In other studies, a marked decrease in Pao_2 levels was observed after feeding 4.7 to 8.0 mL/kg of either human milk or 5% dextrose water by gavage to premature and full-term infants with respiratory distress.[11,12] Gut ischemia has been considered a prime requisite for production of NEC.[6] The bowel that is compromised by perinatal asphyxia, respiratory distress syndrome, and exchange transfusions, which are recognized causes of gut ischemia and also recognized associations of NEC,[6] may then be subject to additional insult by the bradycardia and hypoxia that may result from feeding.

Tejani et al[13] observed a decrease in the blood pH and an increase in the blood lactate level shortly after ingestion of 1.75 g/kg of dextrose by formerly hypoxic premature and term infants. The authors attribute the lactic acidosis to hypoxic injury of the mechanism for glucose transport, resulting in malabsorbed intraluminal carbohydrate, which is then converted into organic acids. They hypothesize that malabsorbed carbohydrate may, by bacterial action, be the source of the gas of NEC pneumatosis.

Cardiac Function in Primary Hypothyroidism

John T. Hayford, MD; Richard M. Schieken, MD; Robert G. Thompson, MD

• Cardiac chamber dimensions and myocardial function were studied in 15 children with primary hypothyroidism prior to and after thyroxine therapy. Small pericardial effusions were detected in 11 of 15 subjects before therapy, which resolved in nine of 11 subjects after initiation of thyroxine replacement. There was no association between the severity of the thyroid failure and the presence of effusion, and no evidence of cardiac compromise due to effusions. No significant abnormality in cardiac chamber or myocardial dimensions, systolic time intervals, or indices of myocardial contractility was detected among the hypothyroid children as compared with a normal population. Neither myocardial dimensions nor contractility indices changed significantly on reestablishment of normal thyroxine concentrations with exogenous hormone. These data refute the existence of a myocardiopathy associated with hypothyroidism in children.

(*Am J Dis Child* 134:556-559, 1980)

The effect of hypothyroidism on cardiac function in children is, to our knowledge, incompletely characterized. Significant abnormalities in left ventricular function have been documented among hypothyroid adults. These observations dictated cautious institution of exogenous thyroid hormone in myxedematous adults to avoid myocardial decompensation. Whether a compromise of myocardial function exists among hypothyroid children is not well documented. To evaluate this possibility, myocardial chamber and muscle dimensions, systolic time intervals, and indices of ventricular performance were studied echocardiographically in a group of children with primary hypothyroidism prior to and after thyroxine therapy.

SUBJECTS AND METHODS

Fifteen subjects, 13 females and two males, first observed at the pediatric endocrine clinic with historical, clinical, and laboratory evidence of primary hypothyroidism had echocardiographic evaluation of myocardial dimensions and function prior to (Table 1) and after (Table 2) initiation of L-thyroxine replacement therapy. The study population was heterogeneous with respect to the cause of the hypothyroidism, four of 15 having a diagnosis of congenital hypothyroidism and the remainder having acquired hypothyroidism, primarily due to chronic lymphocytic thyroiditis. Subject 11 was unique in that her hypothyroidism was secondary to thyroidectomy for papillary follicular carcinoma. Other than for this subject, the duration of the hypothyroidism was not easily documented. The initial echocardiograms were obtained at the time of diagnosis prior to the initiation of replacement hormone. Repeated echocardiograms were obtained at follow-up examination, at which time all subjects were receiving full-replacement thyroxine doses.

Echocardiograms were performed using an echocardiograph with a 3.5-mHz transducer. Tracings were recorded on a strip chart at a constant paper speed of 100 mm/s. Left ventricular diastolic dimension and left ventricular systolic dimension were measured in the standard manner.[1] Systolic time intervals were measured from the echocardiographic aortic value tracings. The preejection period (PEP) was measured from the Q wave of the standard lead II of the ECG to the first rapid opening deflection of the valve leaflets. The left ventricular ejection time (LVET) was recorded as the interval from opening to closing of the aortic valve leaflets.[2] The measured PEP, LVET, and calculated ratio PEP/LVET were compared with the expected normal values for age.[3] Percentage change in left ventricular dimensions and velocity of circumferential fiber shortening were calculated using the echocardiographic LVET according to the method of Gutgesell et al.[3] Heart rate was calculated from the R-R interval of the ECG. Serum thyroxine (T_4) and thyroid-stimulating hormone (TSH) were measured by radioimmunoassay in the hospital clinical laboratory, normal ranges being 4.5 to 12.5 μg/dL for T_4 and 0 to 10 μU/mL for TSH.

Statistical analysis of data using paired *t* tests, analysis of variance, and linear correlation was done by routine procedures available within a computerized statistical package[4] or on a programmable statistical calculator. Unless otherwise noted, summary data are expressed as mean and SEM.

RESULTS

All 15 subjects were hypothyroid at the time of diagnosis, mean serum T_4 concentration being 1.0 ± 0.2 μg/dL (range, < 0.1 to 2.5 μg/dL). Thyroid-stimulating hormone concentration was noticeably elevated in all subjects, the mean serum TSH concentration being 533 ± 81.6 μU/mL. At follow-up examination, all subjects showed clinical signs of resolution of their hypothyroidism. No subject had clinical or chemical evidence of hyperthyroidism induced by their replacement thyroxine. Although the serum T_4 concentrations were within the normal range for all subjects at their follow-up examination (mean $T_4 = 10.3 \pm 1.6$ μg/dL), the TSH concentration was incompletely suppressed by thyroxine replacement in six of 15 subjects (Table 2). Three of these subjects were less than 1 year of age and had relatively brief intervals between initiation of thyroxine replacement and follow-up study. Guyda et al[5] have previously noted the sluggish TSH response of congenitally hypothyroid infants during thyroxine replacement. In the older patients with incomplete TSH suppression, two of three had only modest elevations of TSH.

*T_4 indicates serum thyroxine; TSH, thyroid-stimulating hormone; A, effusion absent; P, effusion present; PEP, preejection period; LVET, left ventricular ejection time; and NA, not available—echocardiographic tracing inadequate.

Small pericardial effusions were detectable in 11 of the 15 subjects at the time of diagnosis. The presence of pericardial effusions did not seem to compromise cardiac function in that there was no statistical difference in clinical and echocardiographic indices of myocardial function between subjects with effusions compared with those without effusions. At follow-up examination, the pericardial effusions had resolved in nine of 11 subjects. The two subjects with persisent effusions were not different with respect to initial or follow-up thyroid function tests or with respect to duration of therapy from those subjects in whom effusions resolved.

There was a significant increase in heart rate after initiating replacement with thyroxine ($P < .01$); however, no significant differences in systolic, diastolic, or mean blood pressure were detectable. Cardiac chamber and ventricular wall dimensions were within the normal limits for age prior to thyroxine replacement. No systematic deviation of these measurements from normal were noted. Furthermore, no significant change in these dimensions compared with pretreatment measurements was detected after the reestablishment of the serum thyroxine concentrations within the normal range.

Systolic time intervals among hypothyroid subjects were not statistically different from those observed among euthyroid control populations. The PEP among hypothyroid individuals was less than expected for heart rate in two of the ten subjects (Fig 1), the remainder having PEPs within or greater than expected. Left ventricular ejection time among hypothyroid subjects (Fig 2) showed less deviation from the expected, with three of the 12 subjects falling outside the normal range. Neither the PEP nor the LVET showed a systematic trend in the direction of deviation from normal sub-

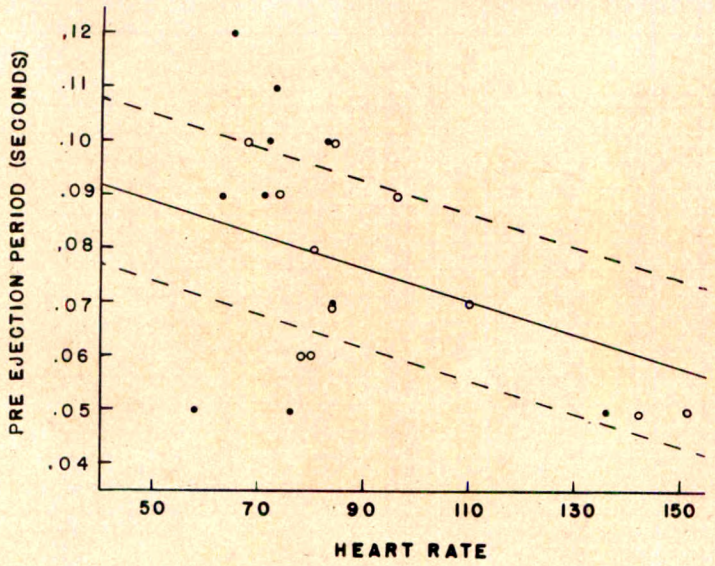

Fig 1.—Preejection period of subjects prior to (closed symbols) and after (open symbols) thyroxine replacement, superimposed on heart rate (beats/min) scaled normative data (mean ± 2 SD) (from Gutgesell et al[3]).

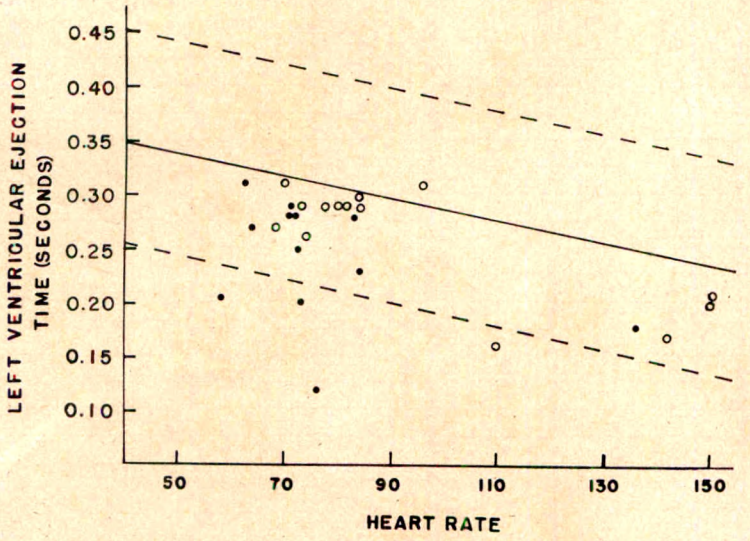

Fig 2.—Left ventricular ejection time of subjects prior to (closed symbols) and after (open symbols) thyroxine replacement, superimposed on heart rate (beats/min) scaled normative data (mean ± 2 SD) (from Gutgesell et al[3]).

jects either prior to or after reestablishment of normal serum thyroxine concentrations. There was no statistically significant correlation between subjects' systolic time intervals or the degree of deviation of the systolic time intervals from normal and the variables of thyroid function. The PEP/LVET ratios were not significantly different than normal. There was a wide scatter in the ratios among hypothyroid subjects, thus reflecting the augmented error inherent in ratios of inversely related variables.

Myocardial contractility, as expressed by the percent of change in left ventricular diameter, was not statistically different from that in a normal population (Fig 3). Three of the 15 determinations among hypothyroid individuals were outside the normal range; however, there was no systematic trend in the direction of this change from normal. Data for velocity of circumferential fiber shortening also showed no significant ($P > .05$) change from normal, although there was wide scatter in the observed compared with expected values. As with the systolic time intervals, there was no significant correlation between the percent change in left ventricular diameter or velocity of circumferential fiber shortening and indices of thyroid function.

COMMENT

Our observations of echocardiographically determined myocardial dimensions and indices of myocardial function show no significant deviation of these values from normal among hypothyroid children. Among the values measured, only heart rate showed a significant ($P < .05$) change on re-

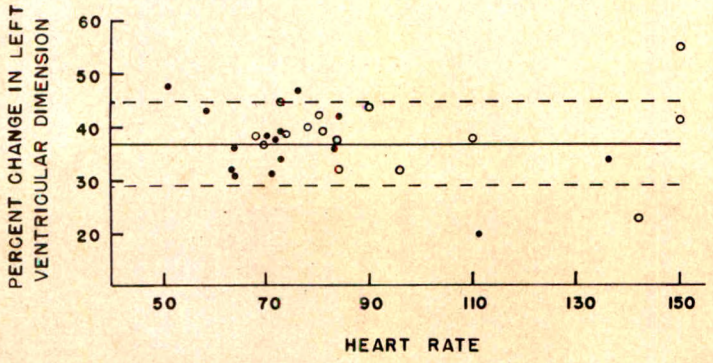

Fig 3.—Percent of change in left ventricular dimension of subjects prior to (closed symbols) and after (open symbols) thyroxine replacement, superimposed on heart rate (beats/min) scaled normative data (mean ± 2 SD) (from Gutgesell et al[3]).

establishment of normal serum T_4 concentrations with exogenous hormone. Although six of the 15 subjects were not euthyroid by the criteria of normalization of TSH concentration at the time of follow-up study, there was no systematic trend in the direction of change of their indices of cardiac function compared with the other nine subjects. This limitation in the data, therefore, should not skew the analysis. The change in heart rate is probably both a direct action of thyroid hormone on the myocardium as well as an indirect effect necessitated by reestablishment of a normal metabolic rate and, therefore, increased peripheral tissue oxygen requirements.[6]

Our observations in hypothyroid children are in contrast to the reported abnormalities in systolic time intervals among hypothyroid adults.[7,8] The reports on adult subjects documented prolonged PEP, shortened LVET, and abnormal PEP/LVET ratios in hypothyroid adults. In addition, Hillis et al[8] documented a significant correlation between systolic time intervals and the degree of thyroid hormone deficiency. No significant correlation was noted in our population between any of the indices of myocardial function and thyroid function tests.

There are limited data on myocardial contractility among hypothyroid adults. Graettinger et al[6] found that severely hypothyroid adults had normal cardiac reserve to exercise stress testing. Our data indicate that hypothyroid children have no alternation in myocardial contractility as measured by the percentage of change in left ventricular dimensions or the velocity of circumferential fiber shortening.

The frequency of pericardial effusions accompanying hypothyroidism appears greater in children than adults. Kerber and Sherman[9] reported that 30% of their 33 adult subjects had echocardiographically detectable pericardial effusions compared with the 73% frequency observed in our younger population. The reason for the discrepancy is unknown; however, the duration of hypothyroidism and age at diagnosis may be important variables. Despite the frequent occurrence of effusions among our hypothyroid subjects, the presence of effusions was not associated with clinically detectable cardiac dysfunction nor with abnormality in echocardiographic indices of cardiac function. Although enlargement of the cardiac silhouette in hypothyroidism is common,[6,9,10] our data suggest that this does not reflect dilated cardiac chambers due to a myxedematous myocardium. Rather, the "cardiomegaly" of hypothyroidism in children is more likely the result of a pericardial effusion in the presence of normal cardiac contractility and chamber size.

Rapid but cautious reestablishment of normal serum T_4 concentrations among hypothyroid subjects is the goal of replacement hormone therapy. Although significant alternations in cardiac function among hypothyroid adults have been reported, our echocardiographic evaluation detected neither any systematic alternation in cardiac chamber or myocardial dimensions nor any decrease in myocardial function among profoundly hypothyroid children. This difference between adults and children may reflect the presence of additional complicating myocardial disease, such as atherosclerotic coronary artery disease, coexisting in the hypothyroid adult population. Our observations in children indicate that myocardial function does not seem to be a limiting factor in determining the rapidity of L-thyroxine replacement therapy.

Cefaclor in Treatment of Otitis Media and Pharyngitis in Children

Samuel E. McLinn, MD

• **The safety and efficacy of cefaclor were compared with amoxicillin trihydrate in the treatment of 130 cases of otitis media, and with penicillin V potassium in 88 cases of streptococcal pharyngitis in two single-blind controlled studies. Patients with otitis media received approximately 40 mg/kg/day of cefaclor or amoxicillin trihydrate for ten days to three weeks; patients with pharyngitis received 20 mg/kg/day of cefaclor or penicillin V potassium for ten days. Overall, patients who received cefaclor for otitis media had fewer acute failures and better total success, especially in cases caused by *Haemophilus influenzae*; however, the difference between cefaclor and amoxicillin was not statistically significant. There also was no significant difference between the clinical effectiveness of cefaclor and penicillin in the treatment of streptococcal pharyngitis. Cefaclor was well tolerated with no serious side effects.**

(*Am J Dis Child* 134:560-563, 1980)

Otitis media and streptococcal pharyngitis, with their high incidence and disturbing relapse rates, are two of the most prevalent infections of childhood. Bluestone has termed otitis media with effusion "the most common diagnosis made by physicians who provide care for children (second only to the common cold)."[1] Studies from various populations have shown that 76% to 95% of all children have at least one episode of otitis media by the age of 6 years.[2,3] Of infants in whom middle ear infections develop at less than 1 year of age, about one half become otitis prone.[4] Permanent structural changes have been reported in as many as 32% of these chronically infected children. Recent literature has shown more insidious complications, such as learning disabilities, lowering of intelligence, and social and language difficulties as a result of impaired hearing.[5-8]

Antibiotics, principally penicillin and penicillin analogs like ampicillin, have contributed to the reduction of such problems. However, there seems to be an increasing number of reports of the development of ampicillin-resistant strains of *Haemophilus influenzae*, both typable and nontypable, which are a major cause of otitis media in young children.[9-14]

Streptococcal pharyngitis also represents a most common and often persistent bacterial infection in children. The selection of the appropriate antibiotic and compliance with the recommended ten-day dosage regimen may be prophylactic as well as therapeutic, possibly preventing both rheumatic fever (an almost extinct entity in this part of the world today) and acute glomerulonephritis. However, it has been estimated that streptococci persist in the pharynx in 10% to 25% of the children who complete a ten-day regimen of penicillin for acute pharyngitis.[15,16] The high persistence and recurrence rates have been attributed to one or more of such factors as failure of the patient to complete the full course of treatment, inactivation of penicillin by β-lactamase-producing staphylococci present in the upper respiratory tract, a high rate of homologous streptococci in household contacts, and the M and T typability of pathogenic isolates.

Cefaclor is a new oral cephalosporin antibiotic with in vitro activity against *Streptococcus pneumoniae*, *H influenzae*, β-hemolytic streptococci, and *Staphylococcus aureus*, organisms commonly found in upper respiratory tract infections of infants and children. This spectrum of activity sug-

gests that cefaclor would be an acceptable alternative treatment for otitis media and streptococcal pharyngitis in pediatric patients.

This is a report of two studies: comparison of the safety and efficacy of cefaclor and amoxicillin trihydrate in the treatment of otitis media, and of cefaclor and penicillin V potassium in the treatment of streptococcal pharyngitis.

MATERIALS AND METHODS

A total of 218 infants and children with acute otitis media (130) or streptococcal pharyngitis (88) were treated as private outpatients in two single-blind controlled studies. Assignment to the drug groups was made according to a computerized random distribution table. Informed consent was obtained from a parent in all cases.

The paired groups were comparable with regard to age and distribution of ages. The otitis media patients ranged from 1 month to 11 years of age, with a mean age of 2.7 years for the cefaclor group and 2.6 years for the amoxicillin group. Twenty-eight (44%) of the 64 patients who received cefaclor and 31 (47%) of the 66 patients who received amoxicillin were younger than 2 years of age. In the patients with pharyngitis, ages ranged from 1 to 17 years, with mean ages of 7.5 years for the cefaclor group and 7.1 years for the penicillin group.

Patients with otitis media received approximately 40 mg/kg/day of cefaclor or amoxicillin trihydrate for ten days to three weeks (mean, 12.4 days) depending on the clinical and bacteriologic response, and patients with pharyngitis received 20 mg/kg/day of cefaclor or penicillin V potassium for ten days. The maximum daily dose of all three antibiotics was 750 mg.

Compliance with the dosage regimen was monitored by requiring the parent to bring the medication bottle to the office visits; the bottle was weighed and compliance was determined by the weight and volume differential.

Bacteriologic methods for patients with otitis media included cultures of ear exudate (obtained by Senturia aspirator[17]) at the beginning of therapy and again 48 hours later. Clinical evaluation was made at the end of therapy and ten to 21 days later.

Throat cultures were obtained from patients with pharyngitis at the start of treatment, and the presence of group A streptococcus was determined by bacitracin disks, 0.04 units (Taxos A disks). Quantitative estimation of 40 colonies or more was required. Follow-up cultures were taken at 12 to 14 days and again two to three weeks after the end of treatment. Specimens were assayed for M and T typing at the Center for Disease Control, Atlanta. All organisms were tested for susceptibility by the Food and Drug Administration Standardized Disk Method.

Evaluation of safety was based on close observation of clinical and laboratory effects. Monitoring included pretherapy and end-of-therapy tests for complete blood cell count, platelet estimation, Coombs' test, BUN, serum creatinine, SGOT and/or SGPT, bilirubin, alkaline phosphatase levels, and urinalysis (including microscopic examination).

RESULTS

Otitis Media

The overall results are given in Table 1. The clinical and bacteriologic success rate for cefaclor was 92% (59 cures in 64 patients) and for amoxicillin 88% (58 cures in 66 patients). The terms of response as used in this study (cure, failure, reinfection, and relapse) are defined in Table 1.

Three cases (5%) failed to respond to cefaclor; the causative organism in two of these failures was *H influenzae* and in the other was *Strep pneumoniae*. Amoxicillin failed to eliminate the causative organisms in six cases (9%); two were *Strep pneumoniae* alone, two were *H influenzae* alone, one was a mixed *Strep pneumoniae* and *H influenzae* infection, and one was β-hemolytic group A streptococcus.

In each group, two patients had initial cures followed by recurrences during the follow-up period ten to 21 days after the end of therapy (Table 1). In the two cases treated with cefaclor, the recurrent organism was different from the original pathogen; these, therefore, could be considered "reinfections" rather than acute "relapses." Two patients who received amoxicillin had a relapse of the original pathogen during the follow-up period.

Although patients who received cefaclor had fewer acute failures and better total success than patients who

received amoxicillin, the difference between the two antibiotics was not statistically significant.

As given in Table 2, of 137 isolates found in the 130 patients, *Strep pneumoniae* was the most frequent—74 isolates or 54%. *Haemophilus influenzae* (nontypable) occurred in 25% (34 of 137 isolates). Eight percent of the organisms were β-hemolytic group A streptococcus, 7% were *Staph aureus*, and 6% were *Neisseria catarrhalis*.

Four patients in the cefaclor group and three in the amoxicillin group had infections due to multiple organisms. All responded satisfactorily except one who received amoxicillin whose otitis media was caused by a combination of *Strep pneumoniae* and *H influenzae*.

Cefaclor seemed superior to amoxicillin against both *Strep pneumoniae* and *H influenzae* (Table 3). For example, 97% of the isolates of pneumococci (36 of 37) were eliminated by cefaclor compared with 89% (33 of 37) by amoxicillin. Against *H influenzae*, the success rates were 85% (17 of 20) and 79% (11 of 14) for cefaclor and amoxicillin, respectively.

Streptococcal Pharyngitis

There was no difference between the clinical effectiveness of cefaclor and penicillin in the treatment of 88 patients with streptococcal pharyngitis (Table 1). Success rates were 88% and 87%, respectively. Acute failures occurred in three patients of each group. Follow-up throat cultures at 14 to 21 days revealed two relapses attributed to cefaclor and three attributed to amoxicillin.

Four serologic types of group A streptococci were identified by M and T agglutination tests of the strains isolated from cases that were either bacteriologic recurrences or failures. Types 1, 4, 12, and 28 were found, with type 12 accounting for about one half the failures/recurrences. All relapses within the 21 days of the study period were homologous. In two additional cases, treated with cefaclor, recurrence of infection occurred 36 and 45 days, respectively, after the end of treatment, with serologic types different from the original strains. Both were type 12 initially but reappeared as type 2 in one case and as type 28 in the other. Because of the length of time between initial cure and reinfection and the appearance of new serologic types, these two cases were classified as "cures."

Adverse Reactions

Cefaclor demonstrated a low incidence of adverse clinical reactions and abnormal laboratory values. No gastrointestinal symptoms were reported in the 107 children who received cefaclor in these studies nor in the 45 patients who received penicillin. In the 66 patients who received amoxicillin, there was one report of diarrhea attributed to the drug therapy but treatment was not discontinued. Six other children had diarrhea, one had vomiting, and one complained of abdominal pain, but a direct association with amoxicillin was not established.

One case of vascular purpura occurred on the sixth day of treatment in a 5-year-old boy with otitis media due to *Strep pneumoniae* who received 250 mg of cefaclor three times daily. Although there was no history of allergy, cefaclor therapy was discontinued as a precautionary measure; there were no hematologic changes. The patient had responded well and further treatment was not indicated. No petechiae were present at the three-week follow-up visit.

COMMENT

Although *Strep pneumoniae* and *H influenzae* are considered the major targets in the treatment of otitis media in children, group A β-hemolytic streptococcus has been reported to cause from 2% to 8% of the cases[1,18-20] and cannot be considered an unimportant pathogen. One alternative therapeutic agent, trimethoprim-sulfamethoxazole, like cefaclor, has been found effective against both ampicillin-susceptible and ampicillin-resistant *H influenzae*. However, unlike cefaclor, it is not recommended for group A streptococcus.

Just as we must be aware of group A streptococcus as an important cause of otitis media, *Staph aureus* is another easily overlooked potential pathogen. Reports of its incidence range from 2% to 12% of the cases.[1,19] It is often resistant (penicillinase-producing) and the penicillins would not be effective.

Our patient population had approximately 8% of each of these Gram-positive organisms. Choice of an antibiotic that is not effective against both β-hemolytic streptococcus and *Staph aureus* could, theoretically, invite initial failure in 4% to 10% or more of patients. The spectrum of cefaclor includes both group A streptococcus and *Staph aureus* (both ampicillin-susceptible and ampicillin-resistant). Our results in a small number of patients with these pathogens (Table 3) suggest that cefaclor offers an acceptable alternative in the treatment of children with otitis media.

In this study, four children with *H influenzae* resistant to ampicillin but susceptible to cefaclor successfully received cefaclor, an encouraging finding in light of the ongoing problem of increased resistance of *H influenzae* to the penicillin analogs. Although the overall results did not show a substantial difference between cefaclor and amoxicillin in the treatment of otitis media, cefaclor did seem to be slightly better than amoxicillin in the cases caused by *H influenzae*.

It was shown in an earlier report[21] that cefaclor achieved measurable concentrations (0.01 to 7 μg/mL) in the exudate of the middle ear, as did amoxicillin and ampicillin (both 0.01 to 3 μg/mL).

Although all our cases of *H influenzae* otitis media were children and infants 5 years of age or younger, there is evidence that this organism is a more frequent pathogen in the older (school-age) child than formerly thought.[22] This underscores the importance of choosing an antibiotic with proved effectiveness against *H influenzae* in the treatment of otitis media in children of all ages.

Penicillin remains the drug of choice in streptococcal pharyngitis. However, if failure does occur and retreatment is necessary to prevent suppurative complications or to eliminate persistent streptococci from the pharynx, cefaclor is an alternative.

Cefaclor may offer some advantage if, as has been suggested,[23,24] penicillinase-producing staphylococcus is a factor in the failure of penicillin to eradicate group A streptococcus from the pharynx. The cephalosporins have a better record against coagulase-positive staphylococci than do the penicillins.

An important practical factor in antibiotic therapy of children is their willingness to comply with the dosage regimen. In our child patients, the palatability of cefaclor preparations has been rated higher than that of the penicillins.

In these single-blind, randomized, controlled studies, cefaclor was found at least as effective as other often-used medications in treating two of the most common infections of childhood. Its effectiveness in treating otitis media caused by *H influenzae* is particularly notable, and it was well tolerated.

Nonproprietary Names and Trademarks of Drugs

Chronic Otitis Media in Children

Microbiological Studies

Itzhak Brook, MD, MS

• **Aspiration of the exudate through the open perforation was performed in 68 children with chronic otitis media. The middle ear aspirate and a swab specimen of the external auditory canal were cultured aerobically and anaerobically. Seventy-eight isolates were recovered from the middle ears, 99 from the external ear canals, and 95 were present at both sites. Aerobes only were isolated from 33 patients (48.5%), nine (13.2%) had only anaerobes, and 26 (38%) had a culture that grew both aerobes and anaerobes. There were 99 aerobic isolates. Aerobes commonly recovered were *Pseudomonas aeruginosa, Staphylococcus aureus, Proteus* sp, *Klebsiella pneumoniae,* and *Haemophilus influenzae.* There were 74 anaerobes isolated. Anaerobes commonly isolated were anaerobic Gram-positive cocci, *Bacteroides* sp, and *Clostridium* sp. These findings demonstrate the polymicrobial bacteriology of chronic otitis media in children. Cultures collected from the external auditory canals prior to their sterilization can be misleading. Reliable information can be obtained from the ear exudates when collected through the open perforation in the tympanic membrane.**

(*Am J Dis Child* 134:564-566, 1980)

Chronic otitis media in children can be insidious, persistent, and very often destructive, with sometimes irreversible sequelae, such as hearing deficit and subsequent learning disabilities. The bacterial flora of chronic otitis media with perforation has not been studied systematically in pediatric patients with use of good anaerobic techniques, although a few older studies indicated that anaerobic bacteria played an important role in this condition.[1]

The present study was undertaken to determine the bacteriology of chronic otitis media with perforation in children. Modern anaerobic and aerobic methodologies were used in an attempt to compare the bacteria isolated from the external auditory canal with those isolated in the middle ear. This comparison is of particular importance, since in many instances clinicians collect the specimens from the external auditory canal, allowing contamination by skin flora.

From the Department of Pediatrics, University of California School of Medicine, Irvine.

SUBJECTS AND METHODS

Patients

Middle ear exudate was aspirated from children suffering from chronic otitis media with perforation. Sixty-eight children were included in this study. The patients' ages ranged from 4 to 16 years (average, 11 years and 2 months). All suffered from mental retardation of varying severity. All were examined at the outpatient Ear, Nose, and Throat Clinic, Washington, DC, between June 1, 1976, and July 30, 1977, for their chronic otitis media. Patients had purulent drainage and a perforated tympanic membrane, and none had cholesteatoma. History of prior operative procedure was obtained in 16 patients. Five had tympanoplasty, and 11 had placement of ventilating tubes. However, none had tympanostomy tubes at the time of cultures, or three months previously. The duration of the chronic otitis media with perforation ranged from six months to eight years (average, three years and eight months). All patients had received previous courses of antimicrobial therapy for their infection. Eight had received one course, 15 had received two courses, and 45 had been treated three times or more. However, patients received no local or parenteral antimicrobial therapy for at least one month prior to sample collection.

Culture Technique

A culture of the external auditory canal was obtained using a swab soaked in sterile saline solution. The swab was immediately plated for aerobic and anaerobic bacteria. Thereafter, the external ear canal was cleaned of cerumen and pus with a blunt curette when indicated, and was swabbed with povidone-iodine (Betadine) and then with 70% alcohol solution, and allowed to dry for two to three minutes. A repeated culture of the external auditory canal was performed in a similar fashion, to document the sterility of the external canal. Collection of the exudate was done through the perforation in the tympanic membranes using a device consisting of an 18-gauge needle covered by a plastic cannula and attached to a 2-mL syringe. The needle was bent to a 45° angle, and the cannula was slipped forward to cover the tip. When the tympanic membrane was approached via an otoscope, the cannula was retracted and the eardrum was entered through the perforation and the exudate was collected. Thus, no contact was made by the needle tip with the speculum or the auditory canal, and no pus was collected from other than the middle ear.

Microbiological Methods

The aspirated fluid was diluted in 0.5 mL of thioglycolate broth and was immediately inoculated onto aerobic and anaerobic media. Sheep blood agar, chocolate agar, and MacConkey's agar plates were inoculated for aerobes. The plates were incubated at 37 °C aerobically (MacConkey's agar plates) or under 5% carbon dioxide and examined at 24 and 48 hours. For anaerobes, the material was plated on prereduced vitamin K_1-enriched *Brucella* blood agar, and anaerobic blood agar plate containing kanamycin sulfate and vancomycin hydrochloride, and placed into enriched thioglycolate broth (containing hemin, sodium bicarbonate, and vitamin K_1).[2] The brucella plates were incubated in anaerobic jars and examined at 48 and 96 hours. The thioglycolate broth was incubated for 14 days. Anaerobes were identified by techniques previously described.[2] Aerobic bacteria were identified using conventional methods.

Organisms recovered only from the external auditory canal were considered to be a contaminant. Bacteria present in both the auditory canal and the middle ear were listed separately and were added to the total number of middle ear isolates.

RESULTS

One hundred and eight middle ear aspirates were obtained from the 68 patients. In 40 patients, bilateral aspiration was performed, and in 19 of them identical bacteria were isolated from both middle ears. In the other 21 patients, differences were noted between the bacterial isolates of both middle ears; 14 differed in one isolate, four in two, and three in three or more isolates. The major bacteria accounting for these differences were *Pseudo-*

monas aeruginosa in seven instances; *Peptococcus* sp in five; *Peptostreptococcus* sp in four; *Bacteroides* sp and *Staphylococcus aureus* in three each; and *Bifidobacterium* sp, *Lactobacillus* sp, and *Haemophilus influenzae* in two each.

Sterility of the canal was achieved in 63 patients (93%). The organisms surviving the procedure of asepsis were considered to present in the external canal only, even when they were recovered from the middle ear. These microbacteria were *Pseud aeruginosa* in three instances, and *S epidermidis* and *Propionbacterium acnes* in two instances each. The data obtained from these patients are given in Tables 1 and 2 as the total number of isolates in a patient, where each bacterial species is counted once even when it was recovered from both ears.

The bacteriological results from the pretreatment aspiration are given in Tables 1 and 2. Bacteria were recovered from all the patients included in

the study. Seventy-eight isolates were recovered only from the middle ear aspirates, 99 only from the external auditory canals, and 95 were present at both sites. For data analysis, only the 173 isolates recovered from the middle ears were considered.

Ninety-five (55%) of the 173 bacterial isolates recovered from the middle ear aspirate were also isolated from the external auditory canal. Seventy-eight (45%) of the middle ear isolates were only recovered from the middle ear aspirate.

There was a total of 99 aerobic and 74 anaerobic isolates recovered from middle ears of the patients. Aerobic bacteria only were isolated in 33 patients (48.5%) and anaerobic organisms only in nine (13.2%). Mixed aerobic and anaerobic isolates were recovered from 26 cases (38.3%). Thus, anaerobes were recovered from 51.5% and aerobes from 86.8% of the patients studied.

The most common bacteria isolated from the middle ear aspirate, in descending order of frequency, were *Pseud aeruginosa* (48.5%), *Peptococcus* sp (34%), *S aureus* (22%), *Bac fragilis* group (13.4%), *Peptostreptococcus* sp (12%), *K pneumoniae* (10.3%), and *Bac melaninogenicus* (10.3%).

In 17 patients (25%), only one isolate (15 aerobic and two anaerobic) were recovered from the middle ear (see Tables 1 and 2). In the rest of the cases, where mixed anaerobic or aerobic bacteria were present the number of isolates ranged from two to five per specimen (average, three isolates per specimen). The combinations of the different isolates varied; there was no consistent pattern of combinations, except between *S aureus* and *Peptococcus* sp, which occurred in six instances.

The predominant organisms recovered from the external auditory canal were *S epidermidis*, *Pro acnes*, and *Pseud aeruginosa*. There was a statistically significant difference noted ($P < .001$) between the isolation rate of *S epidermidis* and *Pro acnes* from the external auditory canal and the middle ear.

Analysis of the data showed no differences between the organisms recovered in the middle ear and the size of the perforation. However, although not statistically significant, more bacteria were present in *both* external canal and middle ear in patients who had large perforation than in those who had a pinhole perforation.

Pseudomonas aeruginosa and *Bacteroides* sp were more frequently recovered in patients who had a perforation for a longer period of time, or in those who had received treatment with more than one course of antimicrobial agents ($P < .05$). No significant statistical correlations were observed between the duration of perforation or the number of courses of antibiotics administered and other bacteria recovered from the middle ear.

COMMENT

The aerobic organisms recovered in this study are similar to those found in previous studies of chronic otitis media,[3-5] where *S aureus*, *Pseud aeruginosa*, and *Proteus* sp were the major pathogens. The lack of proper techniques for isolation of anaerobes may account for the relatively high rate of negative cultures of middle ear effusions in certain previous studies.[3-5] Isolation of anaerobic bacteria from the middle ear fluid of more than half of the patients reinforces studies from the turn of the century, in which a significant role for anaerobes was indicated.[1] Anaerobes were isolated in 33% to 55% of patients with chronic otitis media in studies where anaerobic methodology was used.[6-9]

Anaerobic microorganisms isolated in those studies were *Bacteroides* sp, *Fusobacterium* sp, and Gram-positive anaerobic cocci, all known members of the normal oropharyngeal flora and occasional pathogens of the upper and lower respiratory tract. The polymicrobial bacteriology of chronic otitis media in children was also demonstrated in our study, where aerobic, faculative, and anaerobic bacteria may play a role in the infectious process.

The possible role of anaerobic bacteria in this infection is also suggested by their higher recovery rate from the middle ear only, as compared with their recovery from the external canal. This is more apparent when *Pro acnes* isolates are deleted from the total number of isolates. Thirty-eight anaerobic strains were recovered from the middle ear only, as compared with seven in the external canal.

Only half of the bacteria recovered from the middle ear were also present in the external auditory canal. Furthermore, external ear canal culture in many cases yielded bacteria that were not present in the middle ear. These findings demonstrate that cultures collected from the external auditory canal prior to its sterilization can be misleading. This is particularly important in the case of *Pseud aeruginosa*, which is more frequently recovered in the external auditory canal than in the middle ear. Although this organism is a common inhabitant of the external auditory canal, it can also be recovered from the middle ear, where it may participate in the inflammatory process. Direct middle-ear aspirations through the perforation in the eardrum are therefore more reliable in establishing the bacteriology of chronic otitis media, and can assist in the selection of proper antimicrobial therapy.

Since the methods of isolation and identification of anaerobes were markedly refined and their classification changed, the usage of these techniques provides a clearer assessment of the bacterial flora of chronic otitis media as it is nowadays. The isolation of anaerobes, all known pathogens of the upper and lower respiratory tracts, suggests a possible role for these bacteria in the cause of chronic otitis media.

Measles-Specific Lymphocyte Reactivity and Serum Antibody in Subjects With Different Measles Histories

Peter J. Krause, MD; James D. Cherry, MD; Jean M. Carney, MD; Morris J. Naiditch, MD; Kevin O'Connor

• Measles hemagglutination-inhibiting (HAI) antibody titers and measles-specific lymphocyte reactivity were studied in subjects who had previously received killed measles vaccine and had been recently reimmunized with live vaccine—persons who previously had atypical measles, subjects with multiple immunizations with live vaccine, adults with a history of measles, and persons with primary measles immunization. Twelve to 18 months after revaccination of former recipients of killed vaccine, all 31 subjects had measles HAI antibody titers ≥10 and only three had lymphocyte stimulation indices (LSI) >2.8. The mean LSI and geometric mean titer of antibody were similar to those of persons who had had natural measles many years ago. One subject who previously had atypical measles had an HAI titer of <5 and an LSI of 0.5; another had an LSI of 6.0 and an HAI titer of 80. Only one of seven subjects who were immunized more than once with live vaccine had an LSI of >2.8 one year later. The finding of measles-specific lymphocyte reactivity and antibody levels in revaccinated former recipients of killed vaccine that are similar to those in persons who had natural measles suggests that the risk of future atypical measles in this group is slight.

(*Am J Dis Child* 134:567-571, 1980)

Atypical measles is a recognized clinical syndrome that occurs following exposure to natural measles in some persons previously immunized with killed measles vaccine.[1-6] Because of the severity of atypical measles, the present national recommendation is to revaccinate all previous recipients of killed measles vaccine,[7,8] even though revaccination is at times accompanied by marked pain, swelling, and erythema at the vaccination site.[9-12] Clinical and laboratory observations suggest that the symptoms of atypical measles and the reactions associated with revaccination of previous killed vaccine recipients both involve the same pathogenic mechanism.[9,13] Recently, we had the opportunity to study 75 previous recipients of killed measles vaccine at the time of revaccination.[9] In this study, we noted that severe local and systemic reactions following revaccination correlated with an exaggerated measles-specific lymphocyte reactivity and low or nonmeasurable measles serum hemagglutination-inhibiting (HAI) antibody titers. These findings in revaccinees supported the earlier observations of Fulginiti et al,[1,12,13] who noted measles skin test positivity in previous recipients of killed vaccine and lack of measurable measles serum antibody in patients at the onset of atypical measles.

In our previous study, revaccination resulted in an antibody response in all subjects with low or undetectable titers in their prevaccination serum samples.[9] However, in three subjects who had severe local reactions at the site of reimmunization, measles-specific lymphocyte stimulation was considerably exaggerated three weeks after revaccination. Since there appears to be a critical balance between the cell-mediated measles-specific immune response and humoral antibody, we have wondered if with increasing time antibody titers in these revaccinated subjects may decrease and the cell-mediated response reciprocally increase, and allow a state of renewed sensitivity to measles virus that on natural exposure would result in atypical measles. In support of this notion is the observation of atypical measles in children who were revaccinated with live vaccine many years after primary killed measles vaccine administration.[5,6]

Since in the past, occasional cases of atypical measles have been noted in persons who as far as could be discerned had received only live vaccine,[14] it has occurred to us that under certain abnormal circumstances, measles-specific lymphocyte sensitization can happen in individuals other than recipients of killed vaccine. Recent trends have led to situations where children have received multiple doses of live vaccine.[15,16] Since one unusual case of measles-associated illness has been reported in a recipient of multiple doses of live measles vaccine,[17] and since we observed an unusual illness in a young, previously vaccinated woman, following reimmunization,[18] we have wondered about the possibility of exaggerated measles-specific lymphocyte reactivity in some multiply vaccinated persons.

To further investigate the aforementioned possibilities, we have performed follow-up measles antibody and measles-specific lymphocyte reactivity studies in the previous participants in our killed measles vaccine-

revaccination study and in several other subjects with diverse measles histories.

METHODS

Study Participants

Thirty-five adolescents and young adults, the majority of whom participated in our previous study,[9] who received killed measles vaccine more than ten years ago, were studied at various times in relation to reimmunization with live measles vaccine. Thirty-one subjects in this group had studies performed 11 to 18 months after reimmunization. An attempt was made to include as many subjects as possible in this group, who at the time of their revaccination with live vaccine in the previous study had marked local reactions with or without additional systemic symptoms. To qualify as a marked local reaction, persistent pain at the injection site with swelling and/or erythema of several days' duration was necessary.

Also studied were five adolescents and young adults who had initially received killed measles vaccine and who one to four years prior to the present study had had atypical measles; 12 children, adolescents, or young adults who had initially received live measles vaccine and who had had one or two reimmunizations with live measles vaccine during several years' time because of poor antibody responses; nine adults who had had natural measles 17 to 28 years previously; 12 adolescents and young adults with no history of measles or measles immunization and no detectable measles serum antibody (HAI antibody titers <5), eight of whom were administered live measles vaccine and were studied three weeks and one year after vaccination. Written informed consent was obtained from all adult study participants and from the parents of participating children.

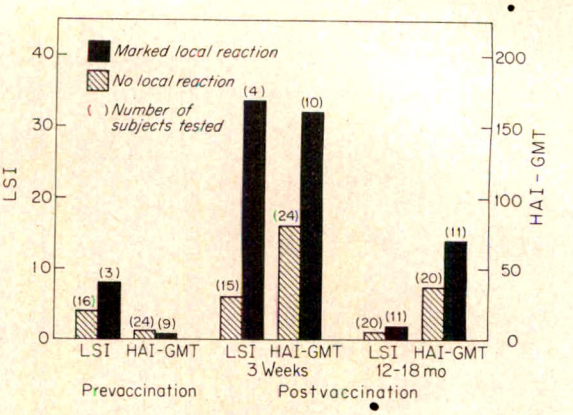
Serologic Techniques

Measles HAI antibody titers were performed on serum by a modification of the method of Hierholzer et al[19] as previously described.[3,5,9,14,15,18,20,21] All titers are expressed as the reciprocals of the serum dilutions.

Lymphocyte Transformation Studies

Lymphocyte transformation studies used commercially available measles complement fixation and control antigens. Methods of lymphocyte separation and harvesting have been previously described.[22] The specific measles-related procedures employed in this study were modified from those of Graziano et al.[23] In brief, 0.2 mL of a 0.5×10^6 lymphocytes/mL solution was incubated in RMPI 1640 medium with 10% fetal calf serum in the presence of 0.02 mL of 1:4 dilution of measles complement fixation antigen, control antigen, no antigen (RMPI medium), or phytohemagglutinin. Because of marked variability of lymphocyte response to different lots of measles antigen, several lots were evaluated. One lot generating adequate response was used in all tests.

After five days, 0.02 mL of tritiated thymidine (100 μCi/mL; specific activity, 20 Ci/μM) was added. Following an 18-hour incubation, the cultures were harvested by means of a multiple-sample harvester. The dried disks were placed in scintillation fluid, counted to obtain the stimulation indices, and the means calculated. Results are reported as lymphocyte stimulation indices (LSI), the ratio of counts per minute of cells incubated with measles antigen to counts per minute of cells incubated with control antigen. A ratio of greater than 2.8 is considered elevated above the background level of the test.



Revaccination with live measles vaccine of former recipients of killed measles vaccine. Measles-specific lymphocyte reactivity expressed as mean lymphocyte stimulation indices (LSI) and geometric mean hemagglutination-inhibiting antibody titers (HAI-GMT) before, three weeks after, and 12 to 18 months after revaccination in subjects with and without marked local reactions at site of reimmunization.

RESULTS

Recipients of Killed Measles Vaccine Who Were Revaccinated

Of the 35 former recipients of killed vaccine enrolled in the present study who were revaccinated previously,[9] 11 had marked local reactions following reimmunization and 24 had no significant reactions. In Fig 1 and Table 1, measles-specific lymphocyte reactivity and HAI antibody titers before, three weeks after, and 12 to 18 months after revaccination are analyzed by the presence or absence of marked local reaction. In both groups—those with marked local reactions and those without—there is a similar lymphocyte reactivity and antibody pattern. Prior to revaccination, the mean LSIs were elevated and the geometric mean titers (GMT) of HAI antibody were low. Three weeks after reimmunization, mean LSI and GMTs increased in both groups, although the rise in LSI in vaccinees without local reactions was less than in vaccinees with marked local reactions. Twelve to 18 months after revaccination, the mean LSI and GMT patterns of the two groups had a reciprocal relationship to prevaccination values. At this point, the mean LSIs were low and the GMTs were about twofold lower than at three weeks, but significantly greater than preimmunization levels.

When LSI and GMT values of subjects with and without marked reactions following revaccination were compared, the following was noted: the LSI was significantly greater before ($P < .05$) and three weeks after ($P < .001$) reimmunization in subjects with reactions than in those without, but these differences had disappeared by 12 to 18 months. The HAI antibody titers were lower initially in those with marked reactions ($P < .05$), increased significantly by three weeks in the same group ($P < .05$), and remained higher at 12 to 18 months ($P < .05$).

Of the total group of former recipients of killed vaccine who were revaccinated, HAI antibody studies were available in 31 subjects at 12 to 18 months of follow up, and in all instances a titer of ≥10 was noted; prior to revaccination, only eight of 33 subjects studied had titers ≥10. Similarly, lymphocyte reactivity data also were available in 31 subjects 12 to 18 months after revaccination, and in 28 instances (90%), the LSIs were <2.8; prior to revaccination, only three of 19 (32%) subjects studied had LSIs <2.8.

Table 1.—Measles-Specific HAI Antibody and Lymphocyte Reactivity* in Subjects With Various Experiences With Measles Virus

Former Recipients of Killed Measles Vaccine Who Previously Had Atypical Measles

Lymphocyte and antibody studies were not available prior to the development of atypical measles in the five subjects studied. One subject was evaluated seven days after onset of the disease. He had an initial HAI antibody titer of 10, which increased to ≥1,280 during the acute illness and fell to 20 eighteen months later. The LSI at seven days was elevated to 9.6 and decreased to 0.4 at 18 months. Of the five subjects with atypical measles evaluated at one year or more after their illnesses, four had HAI antibody titers of ≥20, while one had a titer of <5; the latter subject had an LSI of 0.5. The mean follow-up LSI of the five subjects was 1.7 ± 1.0 (Table 1), with only one of the five being >2.8. The LSI in this latter study participant was 6.0 and the HAI antibody titer was 80.

Subjects Vaccinated More Than Once With Live Measles Vaccine

In this category, there were 12 subjects. Eleven of the 12 participants had HAI antibody titers performed prior to a second live measles vaccination and were found to have values of <5. The remaining subject was not studied before reimmunization, but was noted to have an HAI antibody titer of <5 three weeks after revaccination. Measles-specific antibody and

lymphocyte responses following revaccination are given in Tables 1 and 2. Three of ten subjects studied three weeks after revaccination still had HAI antibody titers of <5, and the two subjects of the original 12 not studied three weeks after reimmunization were found to have HAI antibody titers of <5 one year later.

Prior to reimmunization with a second live vaccine, the LSIs of two of seven subjects studied were >2.8, and the mean was 4.3 ± 1.9; one year after reimmunization, one of five subjects restudied had an LSI of >2.8. Four study participants who failed to seroconvert after reimmunization were reimmunized a second time (subjects 8 through 11 in Table 2). Three weeks after this third vaccination, two of the four had very high LSIs; one year later, both had measurable HAI antibody titers and LSIs that were <2.8. None of the 12 subjects revaccinated had clinical reactions associated with the reimmunization procedure.

One additional subject was retrospectively studied. This 19-year-old woman had had live measles vaccine with γ-globulin at age 4 years and a second live vaccination at age 9 years.[18] She was revaccinated a third time during a measles epidemic. Pain, swelling, and erythema of four days' duration occurred at the vaccination site, and systemic complaints of cough, coryza, and eye pain persisted for two weeks. Following the generalized symptoms, a pruritic rash occurred, which lasted ten days. One year after this woman's last measles immunization, the LSI was 0.7 and the measles HAI antibody titer was 320.

Subjects Who Had Had Natural Measles

In this group, nine adults who had had measles 17 to 28 years previously were evaluated. All had measles HAI antibody titers ≥10 and none had LSIs >2.8. The mean LSI in this group was 1.4 ± 0.2, with a range of 0.8 to 2.8.

Subjects With No History of Measles or Measles Immunization and Serum HAI Antibody Titer <5

In this category, there were 12 adolescents and young adults, eight of whom were given live measles vaccine. In six subjects in whom measles-specific lymphocyte reactivity studies were performed prior to immunization, the mean LSI was 1.4 ± 0.4, with a range of 0.3 to 2.8. One subject in this group, a 20-year-old man, had an LSI of 2.8. He had no record of either past measles or immunization; unfortunately, this subject did not participate in follow-up studies so that further evaluation was not possible. Six subjects, two of whom were studied prior to immunization, were evaluated one year after immunization. The mean LSI of this group was 1.8 ± 0.3, with none of the indices being >2.8. One participant had an HAI antibody titer of <5 at the one-year follow-up; the LSI in this subject was 1.3.

COMMENT

The study of measles-specific lymphocyte reactivity has resulted in inconsistent results in many laboratories and large differences in LSIs between different investigators. In 1975, Graziano et al[23] reported "a reliable and reproducible system" for the demonstration of specific lymphocyte reactivity. Their method uses autologous plasma in the cell culture system. Since we were initially concerned with the possibility that plasma that might contain measles antibody could alter the test results, we modified the test procedure and used fetal calf serum. This modification considerably reduced the sensitivity of the test, but proved to be satisfactory for our initial studies.[9] In this present trial, it might have been useful to utilize the more sensitive autologous plasma technique so that some reactivity could have been shown in lymphocytes from live virus vaccinees and from persons who had natural disease in the past. However, since our major concern was aberrant responses, it seemed more appropriate to us to use our original method, so that comparisons with our original study could be made.

A key factor in the measurement of specific lymphocyte reactivity and the reason for difficulty in many laboratories is the measles antigen. In general, the test in our laboratory has only been successful with two specific lots of measles CF antigen. It is our understanding that Graziano et al have also noted success with only certain lots of antigen (personal communication, M. R. Mardiney, Jr).

The results of our previous study suggested that the presence of exaggerated measles-specific lymphocyte reactivity in association with low or nonmeasurable levels of serum antibody was important for the occurrence of aberrant reactions on exposure to measles virus.[9] In this regard, the findings in the present study are encouraging. Of the 36 previous recipients of killed measles vaccine who were studied one year or more after revaccination with live measles vaccine or after the occurrence of atypical measles, the mean LSI was only 1.5 ± 0.2, and only three subjects had indices >2.8. These three subjects in this grouping had LSIs that were ≥4, but each also had a serum HAI antibody titer that was ≥40. These findings suggest that in the majority of instances, infection with measles virus in former recipients of killed vaccine leads to a persistent antibody response and the suppression of the exaggerated cell-mediated immune responsiveness.

The persistent elevation of measles-specific LSIs in three study participants indicates the need for continued observation. However, the high levels of serum antibody 12 to 18 months after reimmunization (Table 1 and Fig 1) is encouraging since we noted in the previous study that no participant with a measles HAI antibody titer of >20 had a severe local or systemic reaction following revaccination.[9] If in the future the antibody titers in these subjects decrease to lower levels and lymphocyte reactivity remains elevated, then perhaps there will again be the risk of atypical measles.

One patient who had atypical measles in the past was found to have an HAI antibody titer of <5. The LSI in this instance was only 0.5. While this individual may not be protected against further measles infection, the question of revaccination deserves careful consideration. A severe reaction with reimmunization seems unlikely with an LSI of 0.5; however,

there may be other unidentified mediators that could lead to an aberrant response. On the other hand, recurrent atypical measles would almost certainly be more severe if it were to occur than a reaction associated with vaccine administration. If the overall herd immunity of the population is good, then individuals such as the previously mentioned subject need not be revaccinated.

The group of subjects who received two or three doses of live measles vaccine are unusual in that all were preselected because of an HAI antibody titer of <5 prior to the first or second revaccination. Although one of the four subjects who was studied one year after the second immunization had an elevated LSI of 8.6 and a HAI antibody titer of <5, suggesting possible susceptibility to severe vaccine reaction, no abnormal clinical response occurred after a third immunization. Three weeks later, the LSI was only 1.8 and the HAI antibody titer was 10. This perhaps suggests that in the presence of low or absent antibody, multiple revaccinations with live measles vaccine may not result in serious consequences even though the in vitro cell-mediated immune response is exaggerated. However, a larger group should be studied to verify this. In addition, these studies do not answer the question relating to possible "hypersensitization" since all revaccinees in the study had HAI antibody titers that were <5. In spite of a normal LSI and antibody titer one year after reimmunization in the 19-year-old woman we studied, her vaccine-associated reaction is disturbing. Also cause for concern was the unusual illness in the multiply vaccinated adolescent girl described by St Geme et al.[17]

The observation of an LSI of 2.8 in one young man with a history of neither immunization nor natural measles is worthy of comment. Most probably, this man had previous experience with measles virus even though he was unaware of it. Our recent survey in the student population revealed a poor correlation between history and measles antibody; of 40 subjects who denied vaccine or measles in the past, 88% had measles antibody.[18]

At the present time in the United States, available data would suggest that about 10% of older adolescents are measles-susceptible.[18] This is reflected in recent measles outbreaks in colleges and at military bases.[18,24] We have pointed out that history is unreliable in determining the susceptible individuals in this age group.[18] Therefore, control measures will need to employ a serologic screening program or, alternatively, vaccination of nine immune subjects for each measles-susceptible subject. Our expressed position favors selective immunization on the basis of serologic screening data as the method of choice in reducing the number of susceptible subjects in the older adolescent and young adult group.[18] However, it is our impression that our view is considered impractical by many authoritative persons concerned with immunizations.[25] Since there is no easy solution to the problem, it is quite probable that outbreaks of measles will occur on military bases and in colleges, and mass immunization programs will be used for disease control. We hope these pending situations can be anticipated so that studies of vaccine complications in previously vaccinated and perhaps sensitized persons can be critically evaluated.

Isotopic Cisternography in Tuberculous Meningitis of Childhood

Emire Özdirim, MD; Kalbiye Yalaz, MD; Günaydin Erbengi, MD

• The changes in the CSF circulation and absorption are valuable in the diagnosis and management of tuberculous meningitis. We describe the isotopic cisternographic analysis of 45 children with tuberculous meningitis and 30 children with purulent meningitis. The cisternographic patterns of tuberculous meningitis consist of (1) obliteration of CSF space at the level of basal cisterns or cisterna Sylvii and (2) ventricular entry of radiopharmaceutical without clearing by 24 hours (communicating hydrocephalus). None of the patients with a definite diagnosis of tuberculous meningitis demonstrated a normal CSF flow pattern. Thirty patients with purulent meningitis underwent isotopic cisternography. Sixteen of 30 patients demonstrated a normal CSF flow pattern, 3 had mild hydrocephalus, 6 had obliteration of the subarachnoid space at the level of cisterna Sylvii at either side, 3 had delay of CSF flow, and 2 had abnormal CSF collection due to a posttraumatic dura defect.

(*Am J Dis Child* 134:572-574, 1980)

Tuberculous meningitis is still a serious health problem in Turkey. The complications and the mortality have been markedly reduced with the use of antituberculous drugs and steroids.[1-3] The onset of symptoms of tuberculous meningitis is usually acute in infancy and gradual or vague in older children.[2,3] Signs of meningeal irritation may appear relatively late in the disease.[4] Complications in the acute phase and long-term sequelae are related to the stage of the illness at which the therapy is started.[4] A deterioration of the clinical state in tuberculous meningitis may be due to development of vasculitis, which is a common finding, and hydrocephalus. Alleviation of hydrocephalus by the use of a ventriculoatrial shunt reduces the neurologic complications of tuberculous meningitis considerably.[4-6] In order to reach an early decision about the necessity of the surgical procedure, it is essential to examine the dynamics of the CSF. Assessment of the CSF dynamics by means of radioactive material introduced into the subarachnoid space is a convenient method of study.

We report herein the data on CSF flow in tuberculous meningitis and purulent meningitis by use of isotopic cisternography and evaluate the diagnostic value and the benefit of the shunt operaton in tuberculous meningitis patients in whom hydrocephalus has developed.

PATIENTS AND METHODS

The first group consists of 45 patients with tuberculous meningitis. Their ages varied from 4 months to 11 years. Nineteen (42%) of them were girls, and 26 (58%) were boys. The diagnosis of tuberculous meningitis was made by clinical history, physical and neurologic findings and CSF examination, evidence of tuberculosis elsewhere in the body, history of contact with tuberculosis, and identification of tubercule bacilli in CSF or in gastric washings. All 45 patients had CSF findings of tuberculous meningitis such as increased number of lymphocytes and elevation of protein content and low glucose value on more than one occasion. Data that are considered positive for

tuberculous meningitis besides CSF findings are given in Table 1.

The second group consists of 30 patients with bacterial meningitis. Their ages varied from 4 months to 13 years; nine were girls (30%), and 21 were boys (70%). These patients were selected from a group of patients with purulent meningitis who had been improperly treated or who had recurrent meningitis as seen by clinical history, physical examination findings, and laboratory study of the CSF.

Isotopic cisternography studies were carried out on a gamma camera after 1 to 2 μCi of Tc 99m human serum albumin were injected into the lumbar subarachnoid space. Images were taken with the patients in anterior and lateral positions at 2, 6, and 24 hours.

RESULTS

When the radiopharmaceutical is injected intrathecally into the lumbar subarachnoid space, it normally reaches the basal cisterns in one to two hours, the frontal poles and Sylvian fissures in three to six hours, the cerebral convexities by 12 hours, and the sagittal sinus area by 24 hours. Following an intrathecal spinal injection, radioactivity is not normally detected in the ventricular system, probably reflecting the net CSF pathways from the ventricles into the remainder of the CSF space. The radionuclide normally appears to flow into all anatomic structures entered by CSF, except the ventricles.[7-9]

Isotopic cisternograms showed abnormal CSF flow patterns in all of the 45 patients with tuberculous meningitis (Table 2). The findings were as follows: obstruction of the isotope flow in the basal cisterns in 33 cases bilaterally, obstruction of the isotope flow in the cisterna Sylvii in 12 cases bilaterally, entry of the radioisotope into the lateral ventricles without clearing by 24 hours (communicating hydrocephalus) in all of the 45 patients with meningitis (Fig 1 and 2). The observations were made at 2 hours, and no changes were noted at 6 and 24 hours.

Isotopic cisternography was also performed on all patients in the control group with purulent meningitis. The findings of the control group were as follows: normal CSF flow in 16 cases, delay of the isotope flow in 3 cases, obstruction in isotope flow in cisterna Sylvii (unilaterally) in 6 cases (Fig 3), mild hydrocephalus in 3 cases, and dural defect in 2 cases.

COMMENT

Recently, the subarachnoid injection of a radioactive substance for evaluation of CSF flow has received widespread attention. Isotopic cisternography has been used in children for the evaluation of hydrocephalus, CSF leaks, and abnormal communication of the CSF space. Isotopic cisternography is an extremely valuable diagnostic tool in the diseases that may cause abnormal CSF flow.[8,9]

Abnormal CSF flow due to alteration of the structure of the subarachnoid space is probably one of the earliest and most consistent manifestations of tuberculous meningitis.[10] The CSF flow pattern in tuberculous meningitis, which can be demonstrated clearly by isotopic cisternography, has distinct features when compared with normal and purulent meningitis. Obstruction of the isotope flow at the basal cisterns (which occurred in most cases) at the cisterna Sylvii and especially entry of the radioisotope into the lateral ventricles without clearing in 24 hours were the most prominent findings of our studies. None of the patients with a definite diagnosis of tuberculous meningitis demonstrated usual CSF flow. These findings do not correlate with the duration of the illness. Ventriculoatrial shunt was performed on six patients with the cisternographic diagnosis of communicating hydrocephalus due to tuberculous meningitis. Each patient had elevated ventricular pressure, and the CSF protein level was lower than 100 mg/dL. Five of these six patients had an excellent recovery. One patient who was in deep coma prior to operation died a few hours after the shunt procedure.

In the purulent meningitis cases, the purulent material was widely distributed but tended to accumulate over the convexity of the brain into the depth of sulci in the Sylvian fissures and along the major veins and venous sinuses. At the undersurface of the brain, the purulent material was concentrated within the basal cisterns and about the cerebellum. Due to varied clinical presentations, the location of cerebral inflammatory lesions is difficult.[11]

In our study, a normal CSF flow pattern was found in 16 of 30 patients with purulent meningitis. Delay in the CSF flow was found in three cases. In three cases, ventricular entry of radioactive substance with clearing in 24 hours was observed. Six of 30 patients with purulent meningitis had an obstruction in CSF in the cisterna Sylvii unilaterally that was suggestive of subdural effusion. Diagnosis was confirmed as subdural effusions by subdural tap in these patients.

In tuberculous meningitis with communicating hydrocephalus, obstruction of isotope flow at the level of the basal cisterns or cisterna Sylvii were always observed. The different abnormalities in CSF flow patterns can possibly be used in the differentiation of tuberculous meningitis from purulent meningitis by isotopic cisternography.

Sonographic Diagnosis of Cholelithiasis in Childhood

Anthony J. Buschi, MD, A. Norman A. G. Brenbridge, MD

• **With the development of new gray scale signal processing, a high level of accuracy has been obtained with gallbladder sonography. Biliary calculi seem to be more prevalent in the pediatric population than is generally appreciated. Two interesting features of childhood cholelithiasis are the increased incidence in patients without hemolytic anemia and the uncommonly high percentage of gallstones visible with plain roentgenograms of the abdomen. Cholecystosonography is offered as an additional method of establishing diagnostic certainty.**

(*Am J Dis Child* 134:575-576, 1980)

Cholelithiasis is more prevalent among the pediatric population than is commonly appreciated.[1-4] It is a frequent misconception that only pediatric patients with hemolytic disorders will exhibit cholelithiasis. Several large series indicate that the majority (a figure in excess of 75%) of children with cholelithiasis do not have a hemolytic disease.[2,5,6] Of course, the incidence of cholelithiasis in children does not approach that of the adult population. Consequently, symptoms readily attributed to cholelithiasis in adults will less frequently be efficiently diagnosed in the pediatric patient in whom there is no hemolytic disorder.

It is of interest that gallstones are more often opaque in children than in adults (50% to 90% vs 20%) and plain roentgenographic studies of the abdomen will often suggest the diagnosis[5,6] (Fig 1). However, as with adults, oral cholecystography will fail in a certain percentage of children with gallbladder disease. Not all of these patients will have roentgenographically visible (opaque) calculi. Although there are circumstances in which the nonvisualizing oral cholecystogram would be sufficient to establish the diagnosis, there may exist a group of patients in whom more diagnostic certainty is required. Cholelithiasis or cholecystitis will be present in 95% of those patients in whom the gallbladder fails to opacify.[7] There are, however, extrinsic causes for nonopacification, such as liver disease, failure to comply with the requirements of the examination, biliary stasis, diarrhea, and malabsorption. Also, some patients have a known or suspected allergy to iodinated compounds such as would be used for an oral cholecystogram.

With this in mind, an ancillary, or even alternate, method of detection currently widely accepted in establishing the diagnosis of cholelithiasis in adults is ultrasound. As ultrasonic interrogation depicts anatomy independently of function, the nonvisualizing gallbladder (hidden to the radiologist) can be viewed on the sonogram and a statement regarding the presence or absence of calculi can be made rather than inferred. An overnight fast is recommended to assure maximal distention of the gallbladder (this can be dispensed with in the acute situation), but no further preparation is necessary except for sedation of infants and young toddlers.

The normal gallbladder is readily detected as an echo-free structure

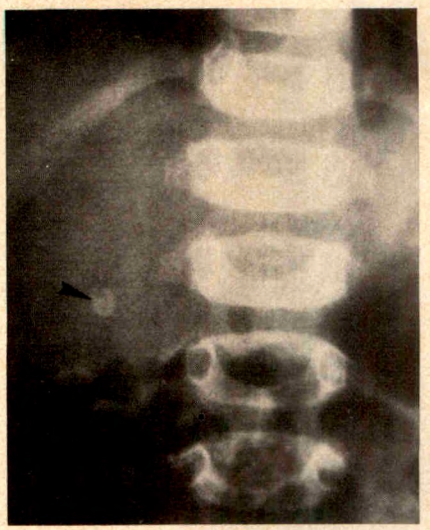

Fig 1.—A 16-month-old female infant with congenital heart disease. Arrowheads indicate two calcified gallbladder calculi.

From the Department of Radiology, University of Virginia Hospital, Charlottesville.

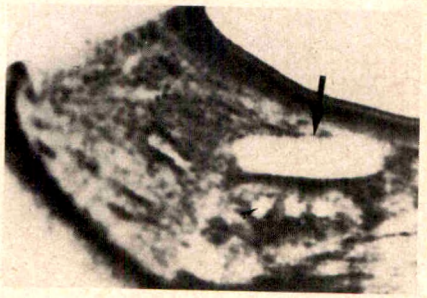

Fig 2.—Sagittal sonogram of right upper quadrant of 11-year-old child. Section is 5 cm to right of midline. Gallbladder (arrow) lies anterior to kidney. (Arrowhead points to renal pyramid.)

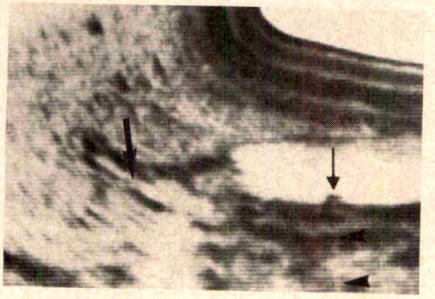

Fig 3.—Sagittal sonogram of right upper quadrant of 7-year-old boy with hereditary spherocytosis. Section was taken to right of midline. Tiny 4-mm calculus (small arrow) casts a faint acoustic shadow (arrowheads). Plain roentgenogram was normal. Large arrow indicates portal vein.

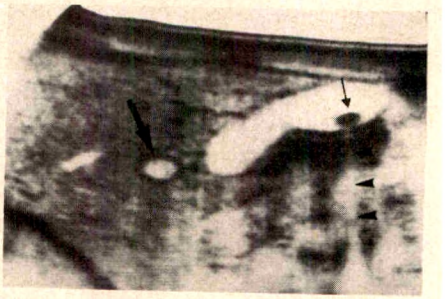

Fig 4.—Sagittal sonogram of right upper quadrant of 16-year-old boy. Small arrow indicates gallstone; arrowheads define acoustic shadow. Plain roentgenogram displayed single, dense calcification within right upper quadrant. Large arrow indicates portal vein.

within the right upper quadrant. It is located just inferior to the free edge of the liver, often immediately anterior to the right kidney (Fig 2). Sonographic detection of calculi (in capable hands) now approaches an accuracy greater than 95%.[8-10] Stones as small as 3 mm can be displayed. The three principal criteria for establishing the diagnosis are a reproducible echogenic focus within the gallbladder lumen, gravity-dependent layering, and a posterior "acoustic shadow" (Fig 3).

An echogenic focus is the sonographic term used to describe the biliary calculus. The size and internal consistency will be recorded as a well-defined cluster of echoes within the echo-free bile. This same cluster of echoes (calculus) can be demonstrated to move into the more dependent position of the gallbladder as the patient is placed in various positions (eg, upright, decubitus).

The curious posterior "acoustic shadow" is a result of the high attenuation of the ultrasound beam by the dense gallstone. This attenuation will result in an absence of sound (ie, an acoustic shadow) beneath the intraluminal stone. Initial work indicated that the shadow was a function of stone size. All stones longer than 3 mm displayed the phenomenon and the demonstration of the posterior shadow was found to be independent of calcium content, shape, surface characteristics, or specific gravity of the stone (Fig 4).[11]

Recent in vitro work has shown that all gallstones will cast an acoustic shadow, regardless of size. However, the production of the shadow was highly dependent on the relationship between the stone and the acoustic-beam width. If the peripheral edge of the acoustic beam encounters the stone, such that a portion of the stone is not within the image obtained, no shadow will be seen. Additionally, if the beam width was wider than the stone diameter, no shadow was perceived.[12] As expected, these variables are easier to control in the experimental situation than in the standard clinical setting. Although all three features may not be evident in every case, the presence of all three assures a diagnosis of cholelithiasis with 100% accuracy.[9] All need not be present for one to be equally confident about the diagnosis.

This series of patients is not large enough to make any reliable statistical analysis of the accuracy of cholecystosonography for children. Among the five patients we have examined with congenital spherocytosis, only that patient whose sonogram is depicted in Fig 3 was found to have gallstones. The exclusion of stones in the remaining cases was made by palpation and inspection at surgery. Our accuracy in a series of 103 adult patients is 98%, with 1% false-negative and 1% false-positive results. The sonographic examination of the gallbladder of children is the same as of an adult. However, as sonography requires skin contact, sedation of those in the younger age group will be necessary and cannot be dispensed with in the uncooperative child.

Endocarditis in the Newborn

Gail A. McGuinness, MD; Richard M. Schieken, MD; Grace F. Maguire, MD

• Three cases of endocarditis confirmed at autopsy were identified in an intensive care nursery during an eight-month period. Echocardiography demonstrated abnormal echoes in the region of the mitral valve in one infant and the tricuspid valve in the other two infants. Both the diverse clinical manifestations of bacterial and nonbacterial endocarditis and the value of echocardiography in the establishment of an antemortem diagnosis are discussed. This previously unusual entity seems to be occurring with greater frequency in neonatal intensive care units that provide vigorous efforts to support severely ill infants.

(*Am J Dis Child* 134:577-580, 1980)

Endocarditis in the neonate has been considered to be an exceedingly rare disease. Prior to the antibiotic era, bacterial endocarditis was a known complication of septicemia in the neonate, usually identified on postmortem examination without the supporting evidence of cultures or Gram's stains.[1] During an hiatus of almost 20 years, the literature yields few reports of neonatal bacterial endocarditis and, only recently, this entity has again been observed in intensive care nurseries.[2,3] In addition, silent aseptic cardiac valve thrombosis has been reported,[4] especially in infants who have been asphyxiated.

We are reporting three cases of endocarditis identified in our nursery during an eight-month period. Echocardiography demonstrated abnormal echoes in the region of the mitral valve in one infant and the tricuspid valve in the other two. These abnormalities were subsequently proved to be indicative of vegetations on postmortem examination. We believe this to be the first report of tricuspid valve endocarditis diagnosed in the newborn by echocardiography. Moreover, we wish to call attention to the protean manifestations of both bacterial and nonbacterial endocarditis in the newborn infant and to report the diverse factors that predispose towards this disease.

From the Department of Pediatrics, University of Iowa Hospitals and Clinics, Iowa City.

Reprint requests to Department of Pediatrics, University of Iowa Hospitals and Clinics, Newton Rd, Iowa City, IA 52242 (Dr McGuinness).

METHODS

Echocardiograms were performed using an ultrasonoscope with a 5-mHz unfocused transducer. M-mode scans were performed from the apex of the left ventricle to the aortic root. The transducer was then repositioned to image sequentially the tricuspid and pulmonic valves.

Bacterial cultures of blood, urine, and CSF were obtained from each infant when clinically indicated prior to starting antibiotic therapy. Cultures were processed by the usual methods[5] by the hospital's Clinical Microbiology Laboratory. Antimicrobial sensitivities were performed by broth dilution.[5]

REPORT OF CASES

Case 1.—This 1,080-g female infant was born after a 26 weeks' gestation and had severe respiratory distress syndrome requiring ventilatory assistance. She was weaned from the respirator after several days, but she never tolerated feedings by nasogastric tube. At 2 weeks of age, a central venous line was placed in the right internal jugular vein and positioned in the superior vena cava for the administration of parenteral nutrition. Two weeks later, episodes of bradycardia and apnea required the reinstitution of ventilatory support. A blood culture obtained from the central venous line showed *Staphylococcus epidermidis* growth, and the infant was begun on a regimen of methicillin sodium. Despite catheter removal, blood cultures continued to show *Staph epidermidis* growth. The infant was transferred to our hospital at 7 weeks of age.

At the time of admission, the child weighed 1,300 g, was malnourished, jaundiced, and in severe respiratory distress. There was a grade 2/6 midsystolic murmur heard best at the lower sternal border. The liver and spleen were palpable to the pelvic brim.

Laboratory data indicated the following values: hemoglobin, 7.4 g/dL; hematocrit, 24%; WBCs, 10,000/cu mm, with 78% neutrophils. The peripheral blood smear revealed many burr cells, schistocytes, and toxic granulations. Platelet count was 8,000/cu mm. Total serum bilirubin level was 12.5 mg/dL, with a direct component of 10.7 mg/dL. The SGOT determination was 210 IU/L, the SGPT determination was 68 IU/L, and the alkaline phosphatase level was 212 IU/L. A chest roentgenogram indicated a normal-sized heart and severe bronchopulmonary dysplasia. An ECG was within normal limits, and an echocardiogram demonstrated a mass in the right atrium attached to the tricuspid valve.

From the time of the infant's admission until death, nine blood cultures had *Staph epidermidis* growth. The minimal inhibitory concentrations to this organism were: ampicillin sodium, 16 μg/mL; cephalothin sodium, 1 μg/mL; chloramphenicol sodium succinate, 4 μg/mL; clindamycin phosphate, > 16 μg/mL; erythromycin lactobionate, 16 μg/mL; methicillin sodium, 8 μg/mL; penicillin G potassium, 16 μg/mL; and vancomycin hydrochloride, 2 μg/mL. Methicillin therapy was discontinued and cephalothin sodium usage begun in a dose of 300 mg/kg/day. While receiving this dose of cephalothin, the serum inhibitory levels were less than 1:2 three hours after drug administration. While receiving 400 mg/kg/day divided every two hours, serum inhibitory and bactericidal levels were 1:16 two hours after administration. The CSF and urine cultures remained negative.

Despite vigorous antimicrobial therapy as just outlined, blood cultures continued to yield *Staph epidermidis* growth. The infant had extensive fissuring and sloughing of the skin, cultures of which had a growth of *Serratia* sp. Hypotension and hypothermia refractory to supportive therapy developed and she died at 11 weeks of age.

The tricuspid valve was thickened and uneven and there was a 10 × 15-mm deep red fibrous vegetation that spanned the plane of the valve orifice

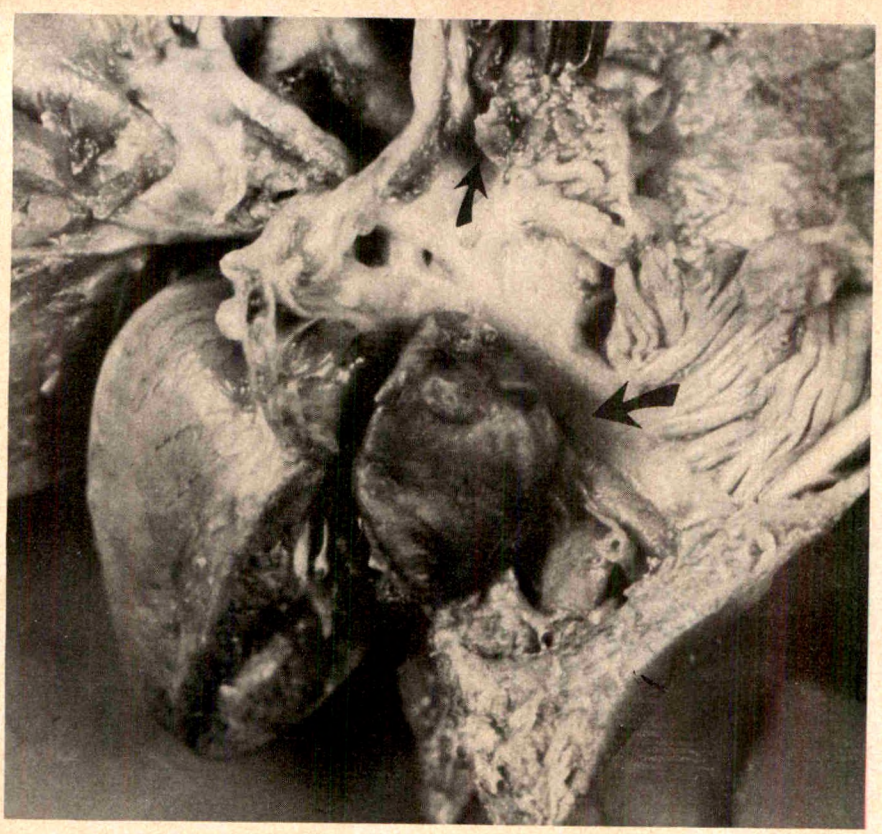

Fig 1.—Large fibrous vegetation spans tricuspid valve orifice (large arrow). Superior vena cava contains mural thrombus extending from vegetation within right atrium (small arrow) (case 1).

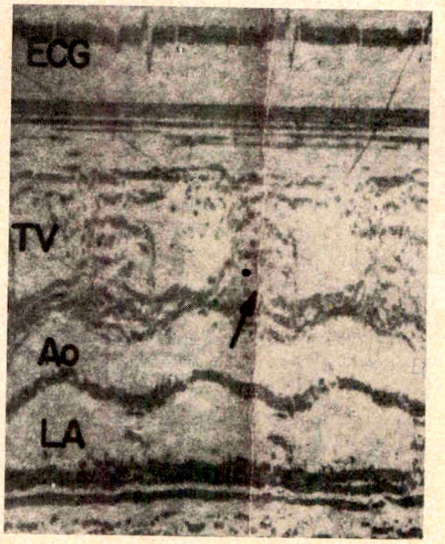

Fig 2.—Echocardiogram. Dense cloud of echoes (arrow) most prominent during diastole appears attached to tricuspid valve (case 1).

(Fig 1). The superior vena cava contained an endothelialized mural thrombus 15 mm in length that extended to the orifice of the vena cava within the right atrium. The tricuspid vegetation consisted mainly of dense fibrin aggregates and hyaline material with few neutrophils and many Gram-positive cocci.

The liver occupied about half of the abdominal volume. Hepatocytes showed degeneration and pyknosis. A ring of dense fibrous tissue surrounded most central veins. The spleen was enlarged, soft, and congested. On microscopic examination, Malpighian corpuscles were not seen.

Postmortem blood cultures showed growths of a mixture of *Staph epidermidis* and a *Serratia* sp. Lung tissue also had growth of *Serratia*, though in small yield. Gram-negative sepsis was never clinically recognized in this infant. However, her extensive skin lesions provided an obvious portal of entry, and it is probable that *Serratia* septicemia contributed to her death.

The echocardiogram disclosed normal dimensions of all chambers and flat septal motion. A dense cloud of echoes appeared attached to the tricuspid valve most prominent during diastole (Fig 2). This was reproducible on several echocardiograms.

CASE 2.—This 2,000-g female infant was born at 36 weeks' gestation after oxytocin augmentation of labor because of maternal eclampsia. Late decelerations of the fetal heart rate were noted, and a cesarean section was performed. The infant was profoundly depressed at birth, requiring intubation and resuscitation. Cultures of the blood, CSF, and urine were obtained, and she was given ampicillin and kanamycin sulfate. She was transported to our hospital seven hours after birth. On admission, the infant had an umbilical artery catheter in place, with the tip at the sixth thoracic vertebra. An umbilical vein catheter had been inserted at the time of delivery for resuscitation and was subsequently removed.

On physical examination, she had a grade 2/6 holosystolic murmur at the left lower sternal border. A gallop rhythm was present, and the liver was palpable 1½ cm below the right costal margin. Chest roentgenogram depicted hyaline membrane disease with cardiomegaly. The ECG showed ST segment changes, and an echocardiogram revealed a left atrial-aortic root ratio of 2:1, with a dense cloud of echoes beneath the mitral valve consistent with a vegetation. This abnormality was recognized premortem, but serious consideration was not given to the diagnosis of endocarditis because of its rarity in the newborn. Therapy with digoxin and furosemide was begun.

Her course was further complicated by acute renal failure. On the fifth day of life, the infant had a bulging fontanelle and a decrease in the hematocrit reading, and she became flaccid and unresponsive. She died shortly thereafter. Subsequently, a blood culture obtained at the local hospital yielded *Escherichia coli* growth.

A clot was present in the umbilical vein. There were multiple 3- to 4-mm vegetations on the mitral valve leaflets (Fig 3). Microscopically, Gram-positive cocci in clumps, as well as neutrophils, were noted within the fibrinous vegetations. There were areas of coagulation necrosis and hemorrhage in the anterior papillary muscle of the left ventricle. The lungs showed widespread atelectasis and hemorrhage along with hyaline membranes. Hepatocytes contained multiple clear vacuoles.

The kidneys showed multiple hemorrhagic infarcts bilaterally. On microscopic examination, there was a large area of coagulation necrosis in the medulla of the left kidney. Cultures of the blood, lung, and kidney infarct obtained at autopsy had growths of *Staph epidermidis*.

CASE 3.—This 2,500-g female infant was born at 43 weeks' gestation. At birth, the

Fig 3.—Multiple 3- to 4-mm vegetations (arrows) are adherent to mitral valve (case 2).

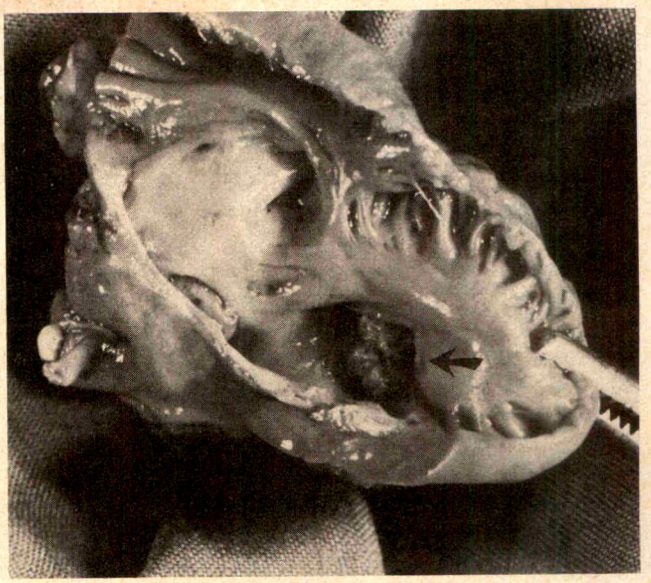

Fig 4.—Irregular vegetation (arrow) is seen on atrial side of posterior and right lateral tricuspid valve leaflets (case 3).

infant was covered with thick meconium and required intubation in the delivery room. On intubation, the vocal cords appeared clean, and no meconium could be suctioned from below the cords. Apgar scores were 2 and 5 at one and five minutes.

For the next several hours, she was free of respiratory distress and tolerated an initial feeding. The initial chest roentgenogram revealed coarse bilateral infiltrates and a normal-sized heart. Cultures of the blood, CSF, and urine were obtained, which were subsequently negative. The infant was begun on a regimen of ampicillin and kanamycin. At 7 hours of age, she was noted to have a respiratory rate of 128/min. Cardiac examination failed to disclose a murmur or gallop. The second heart sound was increased in intensity. The peripheral pulses were diminished. The lung fields were clear to auscultation. A repeated chest roentgenogram showed clearing of the initial infiltrates and a normal-sized heart.

During the next ten hours, the infant's respiratory distress worsened, and ventilatory assistance was instituted. A temporal artery line was established. An echocardiogram was interpreted as normal; however, congenital heart disease and persistent fetal circulation were still considered diagnostic possibilities.

Because of her deteriorating condition and persistent hypoxemia, cardiac catheterization was undertaken at 20 hours of age. The catheter was placed into the left atrium. A single injection was performed to rule out transposition of the great vessels. This demonstrated a normal-sized left ventricle and a normally positioned aorta. Left atrial blood was desaturated. Because of the infant's critical condition, no attempts were made at delineating right-sided cardiac anatomy. After the catheterization, the infant's condition continued to deteriorate rapidly, with acidosis, hypoxia, and hypotension unresponsive to therapy. She died at 32 hours of age. When the echocardiogram was reviewed retrospectively, evidence of a tricuspid valve vegetation was noted.

There was an irregular yellow-white 2 × 3-mm vegetation on the atrial side of the tricuspid valve leaflets (Fig 4). This growth overlay the tricuspid valve and obstructed atrial to ventricular blood flow. Microscopic examination showed no disruption of the valvular endothelium. The overlying vegetation was composed of a bland, hyaline, unorganized thrombus that stained positively for fibrin. Enmeshed within the vegetation were occasional neutrophils, lymphocytes, and RBCs. No bacteria, fungi, or inflammatory foci were noted. Cultures of the valvular vegetation as well as heart blood were negative. All sections of the lungs revealed multiple occlusive fibrin thromboemboli in the small pulmonary arteries and arterioles that were morphologically similar to the tricuspid growth.

COMMENT

Although neonatal endocarditis has been infrequently recognized in the past, its incidence may be increasing because of our ability to support critically ill infants.[2-4] Two recent reports implicated the use of umbilical and central venous catheters in the etiology of both septic and aseptic endocarditis.[2,3] The causative event may be endocardial injury from venous catheters within both left and right atria resulting in the adherence of platelets and fibrin, which leads to the formation of a thrombotic vegetation. Both embolic phenomena and secondary infection of the vegetation, especially with *Staph aureus* and *Staph epidermidis*, were common.

There are only a few reports of bacterial endocarditis in neonates as a complication of septicemia if one requires both histologic and bacteriologic confirmation of the diagnosis. Most of these well-documented cases are in infants with associated congenital heart disease[6-8] although there are rare occurrences in infants without underlying structural anomalies of the heart.[8-10] Vegetations have occurred on the mitral valve, the endocardium of the right and left atria, and the right ventricular septum. Responsible organisms most frequently identified are *Staph aureus*, *Streptococcus pneumoniae*, and β-hemolytic *Streptococcus*. In most of these cases, infective endocarditis was masked by the effects of overwhelming infection such as meningitis or omphalitis so that an antemortem diagnosis was not made.

More recently, attention has been drawn to acute, verrucous, nonbacterial endocarditis in the newborn. Favara et al[4] reported a syndrome of dis-

seminated intravascular and vegetative cardiac thrombosis identified at postmortem examination in 24 infants. It is characterized by thrombosis and cardiac valve platelet masses involving the tricuspid and mitral valve in about equal proportions. This syndrome seems to be confined to the mortally ill newborn with severe hypoxia. Death occurs in the first several days of life, and in some cases, as early as 12 hours after birth. Other investigators have reported similar cases.[11-14]

The three patients described herein demonstrate the diverse causes and manifestations of endocarditis in the neonatal period. One patient (case 1) was of extremely low birth weight and had tricuspid valve endocarditis secondary to a catheter placed in the right superior vena cava for parenteral nutrition, which may have served as a nidus for infection with *Staph epidermidis*. A second patient (case 2) with hyaline membrane disease had *E coli* sepsis and congestive heart failure, subsequently found to be due to mitral valve endocarditis. Complications included renal emboli and secondary infection of the mitral valve with *Staph epidermidis*. The third patient (case 3) was asphyxiated at birth and died at 32 hours of age of progressive hypoxemia unresponsive to mechanical ventilation. At postmortem examination, tricuspid valve nonbacterial endocarditis was identified, with the cause of death being diffuse pulmonary emboli.

The clinical diagnosis of endocarditis in the young infant is exceedingly difficult. As demonstrated by our patients, the presence or absence of a murmur and/or heart failure was not helpful, nor was the chest roentgenogram or ECG. The diagnosis would not have been suspected in these infants without the use of the echocardiogram. Though antemortem diagnosis was made in two of our three patients, in case 3, endocarditis was only identified after death and the vegetation was seen only on retrospective review of the echocardiogram. Two cases of mitral valve endocarditis in young infants diagnosed by echocardiogram have been reported.[15,16] Our additional cases of both tricuspid and mitral valve endocarditis support the value of this noninvasive method to establish the diagnosis.

Echocardiography is safe and can be easily and rapidly performed in the sickest of infants in a neonatal intensive care unit.[17] Echocardiographic demonstration of vegetations in adult patients with bacterial endocarditis was first reported in 1973.[18] The sensitivity of this procedure is related to the size of the vegetation. A study in adults indicated that echocardiography can detect vegetations provided that they are at least 2 mm in diameter.[18] The typical appearance of a vegetation on echocardiography is that of an uneven or irregular thickening of the valve, often with a mass of shaggy or fuzzy echoes attached to the leaflet. Despite this apparent thickening, the motion of the valve is unrestricted.[19] In adults, the echocardiogram has been useful as a prognostic indicator in that patients with vegetations large enough to be documented by this technique have a poor prognosis with medical treatment.[20] Most such patients either die or require operative intervention.

Aggressive and appropriate antibiotic therapy was not successful in case 1. Failure to sterilize the blood suggests that the mural thrombus was acting as a foreign body and continually seeding the bloodstream. Surgical removal of the thrombus was not considered to be a reasonable alternative because of the extremely low birth weight and critical condition of the infant. These cases suggest that endocarditis in the newborn may have an unfavorable prognosis despite antibiotic therapy. Whether surgery has a role to play in the treatment of such infants, as it does in the adult and older child, is unknown.

These three infants demonstrate that endocarditis can manifest itself as a multisystem disease with cardiac, pulmonary, hepatic, hematologic, and renal involvement. The clinician should suspect both septic and aseptic endocarditis in neonates with indwelling catheters, underlying septicemia, and severe hypoxemia and hypotension so that attempts at diagnosis can be undertaken. Echocardiography may provide some information regarding the incidence and natural history of this entity, which seems to be increasing in frequency in neonatal intensive care units.

Encephalopathy in Young Children With Moderate Chronic Renal Failure

James F. Bale, Jr, MD; Richard L. Siegler, MD; Patrick F. Bray, MD

• We studied three boys who had a similar encephalopathy develop during moderate chronic renal failure. The features included cerebellar system dysfunction, seizures, and intellectual and motor retardation. Extensive laboratory investigation failed to disclose an etiology other than chronic azotemia. These cases suggest that the developing nervous system is particularly sensitive to the effects of chronic azotemia. Early dialysis and/or transplantation should be considered in such children in an attempt to modify the serious nervous system abnormalities.

(*Am J Dis Child* 134:581-583, 1980)

The neurologic complications of chronic renal failure are numerous and include polyneuropathy and encephalopathy.[1-4] Although such complications are common, they often correlate poorly with the severity of azotemia.

We studied three boys with moderate chronic renal failure who had a similar constellation of neurologic signs and symptoms. The features included ataxia, hypotonia, intellectual retardation, and minor motor and grand mal seizures. Despite extensive laboratory investigations, no etiology other than chronic azotemia was identified.

REPORT OF CASES

Case 1.—A male infant was the 3,520-g product of an uncomplicated term pregnancy and delivery. The immediate neonatal course was without complications. His subsequent growth was poor, and at 2½ months of age, he weighed only 3,500 g. Examination disclosed a poor urinary stream, and the diagnosis of posterior urethral valves was made. He underwent valve resection but later required multiple surgical procedures including ureteral reimplantation, placement of nephrostomy tubes, suprapubic tube drainage, and cutaneous ureterostomy. Despite these procedures, he remained hydronephrotic and had multiple urinary tract infections and persistent azotemia, with BUN and serum creatinine concentrations ranging from 35 to 70 mg/dL and 1.2 to 2.4 mg/dL, respectively.

At 2½ years of age, he experienced the onset of ataxia and minor motor seizures, and he lost the ability to walk independently. Examination showed growth retardation (weight < third percentile), microcephaly (occipitofrontal circumference < 3rd percentile), truncal titubation, diffuse hypotonia, and diminished deep tendon reflexes. His blood pressure (BP) was normal. Blood smear, CSF profile (protein, glucose, and cell count) and electromyogram (EMG) were normal. An EEG demonstrated high-voltage, diffuse, slow wave bursts, and a computerized tomographic (CT) scan showed mild cortical atrophy. His serum electrolyte values (sodium, chloride, potassium) were normal, and BUN and serum creatinine concentrations were only 30 mg/dL and 1.9 mg/dL, respectively (Table). Clonazepam therapy was started and the seizure frequency decreased.

At 3½ years of age, he had his first grand mal seizure. His BP remained normal, and BUN and creatinine concentrations were 37 mg/dL and 1.9 mg/dL, respectively. Phenytoin sodium was added to the anticonvulsant regimen.

At 4 years of age, he was rehospitalized because of poor seizure control. Examination continued to show hypotonia, truncal ataxia, hyporeflexia, and inability to walk unaided. The BUN and creatinine concentrations were 35 mg/dL and 2.1 mg/dL, respectively. Results of the following laboratory investigations were normal or negative: serum amino acid chromatography, serum copper and ceruloplasmin evaluation, urine arylsulfatase concentration, serum ammonia level, urine homovanillic acid (HVA) and vanillylmandelic acid (VMA) excretion, and CSF examination including IgG-albumin ratio and oligoclonal IgG. Needle EMG and nerve conduction velocities were normal. An EEG showed a slow, dominant rhythm and high-voltage epileptiform discharges. A CT scan continued to show mild, diffuse cerebral atrophy. The anticonvulsant regimen was changed to valproic acid and phenobarbital, which resulted in better control of seizures.

Case 2.—This boy was the full-term product of an uncomplicated pregnancy and delivery. At 3 days of age, the diagnosis of

Renal Function and Metabolic Parameters at the Onset of Neurologic Signs and Symptoms*

Case	BUN, mg/dL	Creatinine, mg/dL	Calcium, mg/dL	Phosphorus, mg/dL	CO_2 content, mEq/L
1					
Ataxia, minor motor seizures	30	1.9	11.2	6.1	16
Grand mal seizures	37	1.9	9.9	4.0	16
2					
Ataxia	64	2.1	10.5	6.4	14
Minor motor and grand mal seizures	78	2.5	7.9	7.5	...
3					
Ataxia	63	3.9	10.9	5.6	21
Minor motor seizures	62	3.3	10.6	4.2	24

*All three children had concomitant intellectual retardation.

posterior urethral valves and secondary reflux nephropathy was made. During the subsequent six months, he underwent several surgical procedures including valve resection, ureteral reimplantation, vesicostomy, and ultimately left nephrectomy. The BUN and serum creatinine concentrations ranged from 40 to 82 mg/dL and 1.1 to 3.1 mg/dL, respectively, during the first 2 years of life.

He sat at 10 months of age and crawled at 15 months. He acquired no recognizable words and never walked.

At 17 months of age, truncal instability appeared. Examination disclosed a small child (height and weight < the third percentile) whose head circumference was at the 50th percentile. He exhibited hypotonia, hyporeflexia, and truncal ataxia. His BP was normal. Laboratory evaluations disclosed the following values: serum electrolyte and serum magnesium, normal; BUN, 64 mg/dL; creatinine, 2.1 mg/dL; CT brain scan, normal; CSF profile, normal; and urine tests for HVA and VMA, negative. An EEG was abnormal with generalized rhythmic slowing. At 18 months of age, minor motor and grand mal seizures began. His renal function, BP, and serum electrolyte values were unchanged (Table). A repeated EEG was again abnormal, now with frequent epileptiform discharges. Phenobarbital and, later, phenytoin were prescribed. During the subsequent months, there was gradual deterioration until his death at 36 months of age. No autopsy was performed.

CASE 3.—This dizygotic twin was the 1,700-g product of an uncomplicated 34 weeks' gestation. The infant experienced mild, transient respiratory distress necessitating supplemental oxygen for 24 hours. However, he remained in the hospital for eight weeks because of poor growth and persistent azotemia (BUN, 50 mg/dL). The diagnosis of hypoplastic kidneys was made, and at 5 months of age, a ureterostomy was performed. He subsequently had frequent urinary tract infections.

He walked at 2 years of age and was slower than his twin sibling in all areas of psychomotor development. At 5½ years of age, he experienced the onset of minor motor seizures. An EEG was abnormal with frequent generalized 2 to 4/s spike-and-wave discharges. His BP was normal. Serum electrolyte and serum magnesium levels were normal. The BUN and serum creatinine concentrations were 62 mg/dL and 3.3 mg/dL, respectively (Table). Treatment with phenobarbital and ethosuximide was started; later, clonazepam was added to the regimen.

The azotemia increased, and at 6½ years of age, he was admitted to the hospital with nausea, vomiting, and a BUN concentration of 170 mg/dL. Because of his severe psychomotor retardation, long-term dialysis or transplantation was not started. Instead, a single peritoneal dialysis was performed, and a low-protein diet high in essential amino acids was started. During the subsequent year, his BUN concentration ranged between 39 and 62 mg/dL.

At 7½ years of age, he was hospitalized because of increasingly frequent seizures. Examination revealed a small child (weight, height, and head circumference all < the third percentile) who exhibited hypotonia, diffuse muscle wasting, truncal ataxia, and a wide-based gait. The BUN and serum creatinine concentrations were 63 mg/dL and 3.9 mg/dL, respectively. Results of the CSF profile, CT brain scan, urine tests for amino acids, tests for serum ammonia and CSF aluminum, needle EMG and nerve conduction velocity testing were normal. The EEG remained abnormal with diffuse, slow activity interspersed with diffuse 2.5 to 3/s spike-and-wave discharges.

During the subsequent six months, uremia became increasingly severe and the child died. No autopsy was performed.

COMMENT

Encephalopathy is a commonly recognized complication of azotemia and consists principally of alterations in mental function and involuntary motor phenomena such as tremor, asterixis, myoclonus, and convulsions.[1-3] Associated features may include cranial nerve abnormalities, cerebellar system dysfunction, and alterations in muscle tone and deep tendon reflexes.[4] Although encephalopathy may occur during acute renal failure, it is more often seen after chronic azotemia and, in adults, as a preterminal event when the glomerular filtration rate (GFR) is less than 10 mL/min.

Baluarte and co-workers[5] described a distinct neurologic syndrome characterized by myoclonus, dysarthria, seizures, dementia, coma, and an abnormal EEG in six children with chronic renal failure secondary to congenital renal disorders. The encephalopathy occurred between the ages of 26 months and 10 years, at a time when renal failure was far advanced (GFR, 5 to 10 mL/min/1.73 sq m).

Unlike the patients reported by Baluarte and co-workers, the encephalopathy in our patients began at a time when renal failure was only moderately advanced (GFR, 15 to 25 mL/min/1.73 sq m). Cerebellar signs and symptoms were prominent at the onset of the encephalopathy, and seizures (initially minor motor) began concurrently or shortly thereafter. All three children exhibited intellectual retardation.

The pathogenesis of uremic encephalopathy in these and other patients remains speculative. In general, the neuropathological findings are nonspecific and consist primarily of diffuse neuronal abnormalities and glial proliferation. However, necrosis of the granular cell layer of the cerebellar cortex is often found and may be related to the prominence of cerebellar signs and symptoms in these children.[6] Most authors attribute the encephalopathy to metabolic derangements, such as accumulation of neurotoxic organic acids and inhibition of cerebral enzyme systems by uremic

toxins.[7,8] Baluarte and co-workers[5] cited an additional mechanism, and they suggested that in their children, the encephalopathy may have been the result of aluminum intoxication. We measured the CSF aluminum concentration for patient 3, and we found it to be normal.

The variable response of the neurologic dysfunction to therapeutic measures makes it difficult to decide when or if to begin therapy. The decision is further complicated by the often poor correlation between neurologic symptoms and the degree of metabolic alteration.[9] In the experience of Baluarte et al,[5] dialysis and successful renal transplantation did not halt the progression of the encephalopathy. In contrast, other authors suggested that in adults, early aggressive dialysis and/or transplantation may improve the neurologic status of most patients.[10] This is particularly true for uremic polyneuropathy.[11,12]

Our experience suggests that the developing nervous system of the infant and young child may be particularly sensitive to the effects of chronic azotemia. Each of our patients exhibited diffuse CNS dysfunction with seizures and intellectual and motor retardation. Despite the fact that the neurologic abnormalities began when the renal failure was only moderately advanced, it is tempting to recommend that such young children with CNS signs and symptoms receive dialysis or transplantation early. Although data to support this recommendation are lacking, such an approach should be considered in an attempt to alter the progression of the serious nervous system dysfunction.

A Lesson in Nutrition

During my early years at The Rockefeller Institute for Medical Research, I had the opportunity of knowing rather well two famous physicians whose nutritional habits symbolize the possibility of adapting successfully to extremely different dietary regimens. One was William Henry Welch (1850-1934), who was the architect of medical and public health sciences in America. The other was Oswald T. Avery (1877-1955), in whose laboratory I worked for 13 years and with whom I remained in close contact to the end of his life. Welch and Avery were approximately of the same height, had received similar college and medical educations, spent most of their lives in academic medicine, remained bachelors, smoked a great deal, took practically no physical exercise, and never tired of talking. But they differed completely in nutritional behavior.

Welch had a gargantuan appetite, with a preference for rich, well-seasoned foods. He was inordinately fond of sweets and was prone to end his meal with several helpings of ice cream—in a period when this meant real cream. He loved wine and hard liquor and seemed proud of the fact that his most violent form of exercise was taking off his shoes at night and putting them on in the morning. He early became obese but remained intellectually active to the end of his life. He died of cancer in his 85th year.

Avery ate sparingly. Two slices of toast, a few leaves of lettuce and several cups of coffee seemed to be his ideal meal. We used to say that he could be in nutritional balance only by fixing atmospheric nitrogen. He never weighed more than 90 pounds during the 30 years I knew him yet he was constantly active either in laboratory work or participating in discussions.... He died of cancer in his 79th year.

RENE DUBOS (*Am J Clin Nutr* 32:2623-2624, 1979).

Outcome of Hepatitis in Children With Acute Leukemia

William Malone, MD, Robert Novak, MD

• The cases of 31 children with acute leukemia and concurrent hepatitis were evaluated for the outcome of their hepatitis. Thirteen of these children had hepatitis B and 18 children had a non-B hepatitis. Chronic hepatitis developed in more than half of the children with acute hepatitis, with the majority of cases being of the chronic, active type. A majority of these children had received at least one blood transfusion in the preceding year. No relationship was seen between the development of chronicity of the liver disease and the management of the acute hepatitis or the state of underlying disease. With the potential for a cure for acute leukemia increasing, a method of reducing the sequelae of hepatitis in children with leukemia is needed.

(*Am J Dis Child* 134:584-587, 1980)

Hepatitis is recognized as a threat to children with cancer because they frequently receive blood-replacement therapy during intensive myelosuppressive therapy. Estimates of the risks of acquiring hepatitis B range from 1% to 20% among children with leukemia.[1-3] Recently, two patients cared for at St Jude Children's Research Hospital, Memphis, who had apparently been cured of leukemia later died of hepatitis and its complications. This led us to review our experience with hepatitis in children with acute leukemia.

REPORT OF CASES

Case 1.—This 20-year-old man was diagnosed as having acute lymphocytic leukemia five years before his death. He was treated according to the "Total Therapy VIII" protocol (first with prednisone, vincristine sulfate and daunorubicin hydrochloride, followed by cranial irradiation and intrathecal methotrexate sodium for CNS prophylaxis, and then maintenance therapy with mercaptopurine, methotrexate and cyclophosphamide)[4] and remained in continuous, complete remission.

One month before this therapy was to be completed, nausea and vomiting developed. On physical examination, he had a low-grade fever and mild scleral icterus. Laboratory evaluation showed an SGOT level of 72 Karmen units (normal level, 6 to 40 units) and his serum contained the hepatitis B surface antigen (HB_sAg). A diagnosis of acute hepatitis B was made. The hepatitis B antigenemia and elevation in transaminase levels persisted for the next 21 months. With the development of marked jaundice in September 1977, a percutaneous liver biopsy was performed; the specimen showed chronic active hepatitis with cirrhosis. Over the next six months, the patient's condition progressively deteriorated despite prednisone therapy, salt restriction, and the administration of diuretics. No autopsy was obtained.

Case 2.—This 19-year-old man was first diagnosed as having acute lymphocytic leukemia 15 years before his death. He was treated according to the Total Therapy III protocol (prednisone and vincristine followed by craniospinal irradiation for CNS prophylaxis and then treatment with mercaptopurine, methotrexate, and cyclophosphamide for maintenance)[5] for three years, at which time his therapy was stopped. He remained in continuous, complete remission. Hepatomegaly and elevated SGOT levels were noted two months after completion of his therapy for leukemia. These abnormalities persisted for 18 months, and a liver biopsy specimen revealed "active portal fibrosis." Review of this biopsy specimen at a later date supported a diagnosis of chronic active hepatitis. A serum sample that had been kept frozen from the time of this biopsy was positive for the HB_sAg.

Hepatomegaly and abnormal transaminase levels persisted for the next four years, at which point he was lost to follow-up for four years. In September 1978, he returned and had obvious hepatic failure: the serum test for HB_sAg was still positive

and liver biopsy specimens showed chronic, active hepatitis with cirrhosis and hepatocellular carcinoma. Treatment with prednisone, diuretics, and salt restriction failed to halt the progressive hepatic failure. At autopsy, the liver showed chronic active hepatitis, advanced cirrhosis, and a massive hepatocellular carcinoma (Fig 1).

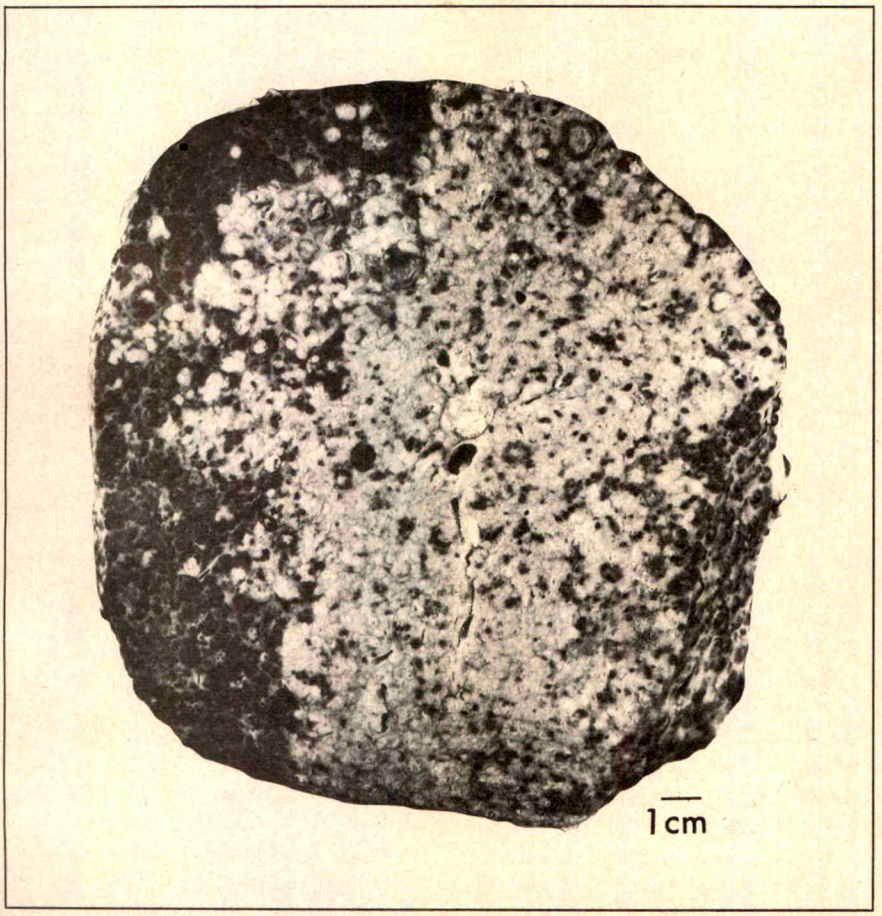

Fig 1.—Cross section through left lobe of liver shows extensive macronodular cirrhosis and massive amount of tumor.

PATIENTS AND METHODS

The medical records of all children with acute leukemia were reviewed for a concurrent diagnosis of hepatitis. Only those children who had had an HB_sAg determination and had isolated hepatitis that was not associated with a generalized infection were included. Chronic hepatitis was defined as the persistence of elevations of serum transaminase levels of 1.5 times the upper limit of normal for more than six months. The clinical record of each patient was reviewed to determine the type and status of the child's leukemia, the relation of the onset of hepatitis to blood transfusion, the management of the acute episode, and the subsequent course and outcome of the hepatitis. The HB_sAg status was determined by hemagglutination assay from 1970 to 1974 and by radioimmunoassay after 1974. Blood for transfusion was from volunteer donors and was screened by the method for determining HB_sAg that was in use at that time. Liver tissue obtained from biopsy or autopsy on any patient in this group was reviewed by two pathologists (who had no knowledge of the clinical data) and was classified according to standard criteria[6,7] as showing either no hepatitis, chronic persistent hepatitis, or chronic active hepatitis.

RESULTS

A total of 31 of the 797 children with acute leukemia had an episode of acute hepatitis as determined by the criteria just stated. Some form of chronic hepatitis developed in 18 patients (Fig 2).

There were 13 patients with HB_sAg-positive hepatitis. Eleven of these cases occurred before 1974. Four of these children had complete resolution of their hepatitis in less than six months and no longer carried HB_sAg. Two children had normal serum transaminase levels but were persistent carriers of HB_sAg. Of the seven patients with chronic hepatitis, six had hepatic tissue examined. Chronic

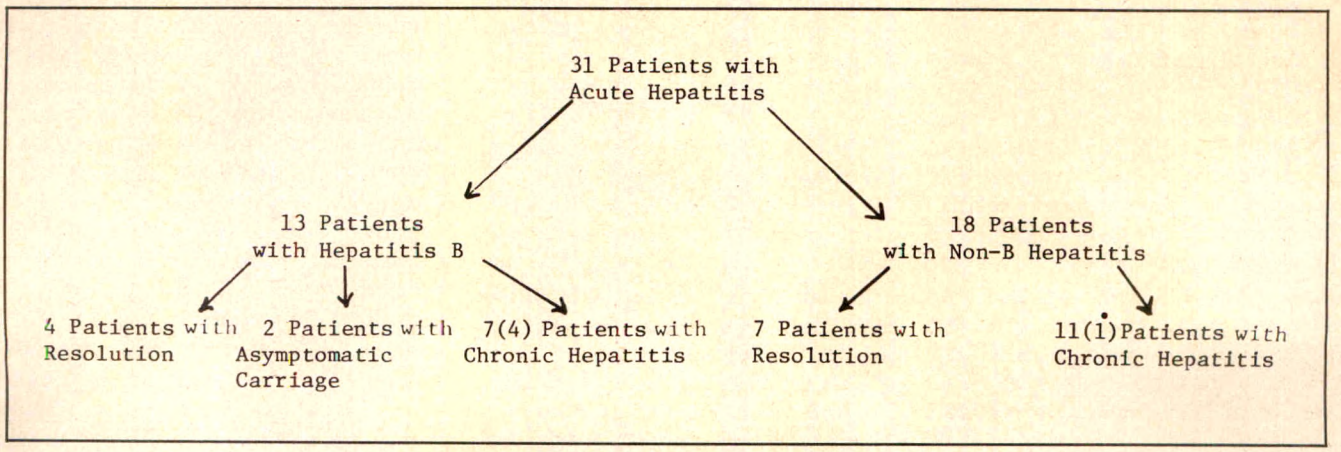

Fig 2.—Outcomes of 31 cases of acute hepatitis in children with leukemia. Numbers in parentheses are numbers of children who died of liver disease.

persistent hepatitis was found in two cases, and chronic active hepatitis with some degree of associated cirrhosis was present in four cases.

Acute lymphocytic leukemia was the basic disease in ten patients and acute nonlymphocytic leukemia was the basic disease in three cases; ten were in remission and three were in relapse of their leukemia. The type and status of the leukemia bore no relation to outcome. All patients had received two or more blood transfusions in the preceding 12 months. Three patients either had completed therapy or had chemotherapy discontinued at the time their hepatitis was diagnosed. All three had chronic hepatitis develop. In eight patients chemotherapy was withheld during the acute phase of the hepatitis (two to four weeks) and then it was resumed; four of these patients showed complete resolution, one became an asymptomatic HB_sAg carrier, and chronic hepatitis developed in three. Two patients had no interruption of therapy, one became a chronic asymptomatic carrier of HB_sAg, and chronic hepatitis developed in one.

Eighteen children had episodes of HB_sAg-negative hepatitis; ten of these cases occurred before 1974. Apparent complete resolution, with a return of serum transaminase levels to normal within six months, occurred in seven children. Chronic hepatitis developed in 11 children. Tissue examinations have been performed in eight of these patients, chronic persistent hepatitis was present in two cases and chronic active hepatitis in six cases.

The underlying disorder was acute lymphocytic leukemia in 16 patients and acute nonlymphocytic leukemia in two patients. Sixteen patients were in remission, and two were in relapse of their leukemia. Again, the type or status of the leukemia bore no relation to the outcome of the hepatitis. Blood transfusions had been administered to 16 of 18 patients in the previous year. The two patients who had not received a transfusion had brief illnesses with complete resolution, which was suggestive of hepatitis A. Two patients had their chemotherapy discontinued when hepatitis occurred; one had complete resolution of liver abnormalities and chronic hepatitis developed in one. Chemotherapy was withheld during the acute phase of hepatitis (two to six weeks) in 14 patients; chronic hepatitis developed in nine of these patients and five had complete resolution. Therapy was not interrupted in two cases; one patient's condition completely returned to normal, while chronic hepatitis developed in the other.

COMMENT

Chronic hepatitis developed in 18 of 31 patients with acute leukemia who had an episode of acute hepatitis. The development of hepatitis is an acknowledged risk in children who require multiple infusions of blood and blood products.[8,9] Twenty-nine of the 31 patients and all 18 patients in whom hepatitis developed had received transfusions in the preceding six months. The relative decrease in the frequency of HB_sAg-positive cases after the introduction of sensative HB_sAg screening methods and the steady frequency of the HB_sAg-negative cases is consistent with what has been observed in previous series of cases of posttransfusion hepatitis.[8,9]

Analysis of hepatitis cases is complicated in patients with cancer because they often receive potentially hepatotoxic agents during therapy.[10,11] The characteristic histologic changes seen in the liver biopsy specimens, the association of the HB_sAg in some cases, and the lack of effect on the course of the hepatic dysfunction from alterations in drug therapy suggest that our cases were not drug related.

Hepatitis Carriers

In the general population, Perman and Grand reported that there is a 10% risk of becoming a carrier of HB_sAg after becoming HB_s Ag-positive.[12] Of these long-term carriers, approximately 60% will have chronic persistent hepatitis develop and 10% will have chronic active hepatitis develop.[13] In our patients with acute leukemia and hepatitis B, nine of 13 (69%) became long-term HB_sAg carriers, at least three of nine (33%) of these long-term carriers had chronic persistent hepatitis, and four of nine (44%) had chronic active hepatitis. This represents a greater frequency of chronicity along with a disturbing increase in the incidence of an aggressive, potentially fatal form of the disease.

In our patients with non-B hepatitis, evidence of chronic hepatitis developed in 11 of 18 patients and at least six had chronic active hepatitis confirmed by analysis of liver biopsy specimens. Studies of non-A, non-B posttransfusion hepatitis in patients undergoing open heart surgery[14,15] have shown an incidence of progression to chronic hepatitis of approximately 40%, with from 23% to 35% having chronic active hepatitis confirmed by analysis of biopsy specimens. This suggests that the course of non-A, non-B hepatitis may not be much worse in our patients with cancer than in the normal host. It also offers the hope that prophylactic regimens that are effective in patients who do not have leukemia might be effective with leukemia.

Possible Beneficial Effects of Hepatitis

Barton and Conrad[16] have suggested that hepatitis in patients with acute myelogenous leukemia may have a beneficial effect on the patients' outcome. Our series is too heterogeneous and our long-term follow-up is too limited to rigorously support or deny this assertion. It is important to remember the limitations of the data presented by these authors, namely that no clear distinction between posttransfusion hepatic dysfunction and drug-induced hepatic dysfunction is made and that no histologic proof of hepatitis is given. Based on the patients in our series, our belief is that the occurrence of hepatitis in a patient with acute leukemia is undesirable. Not only is there a risk of chronic liver disease, but hepatic dysfunction may limit the amount of effective chemotherapy that can be administered at a crucial point in therapy.

Implications for Therapy

As chemotherapy becomes more effective and estimates of a 40% cure

rate[17] in childhood null-cell acute lymphocytic leukemia are made, concern for long-term sequelae and complications of therapy have become more important. The role and value of steroid therapy in chronic active hepatitis is controversial,[18] and no studies have been performed in the population with childhood leukemia. Our data offer no suggestion as to the appropriate management and modification of the potentially immunosuppressive and hepatotoxic chemotherapy these patients require for control of leukemia. Advances in blood-banking techniques have decreased the incidence of hepatitis, especially of HB_sAg-positive hepatitis, after transfusion but will probably not eliminate it.[10] The use of prophylactic γ-globulin administration with transfusion has been shown to be of value in preventing chronic non-A, non-B hepatitis in a small number of patients[15] and deserves a trial in the patient with childhood cancer. To aid in the development of methods of management and of measures to prevent this complication, we must define the problem of hepatitis in childhood leukemia more precisely with firm data from liver biopsy specimens.

Multicystic Ovaries Detected by Sonography

Alan N. Lindsay, MD; Mary L. Voorhess, MD; Margaret H. MacGillivray, MD

• **Four girls with long-standing primary hypothyroidism, three of whom had modest sexual precocity, were found to have multicystic ovaries when evaluated by pelvic sonography. The ovarian lesions were not evident clinically in three of the patients. The cysts regressed rapidly with thyroid replacement. The use of pelvic sonography may show that multicystic ovaries occur more frequently in profoundly hypothyroid girls than has been reported previously. There was a marked discrepancy between baseline plasma luteinizing hormone (LH) levels, which were elevated in three of four girls, and the urinary LH output, which was low or normal. Plasma and urinary follicle-stimulating hormone levels were normal. Two of three girls tested with luteinizing hormone-releasing hormone infusion had attenuated gonadotropin responses, while the third reacted normally. Our hormonal data do not provide an explanation for the cystic ovarian changes and early sexual development.**

(*Am J Dis Child* 134:588-592, 1980)

It is known that precocious sexual development occurs in some children with severe and long-standing primary hypothyroidism,[1-6] but multicystic ovaries have been reported in only a small group of affected girls.[2-11] We describe four hypothyroid patients with multicystic ovaries detected by pelvic sonography, a technique not mentioned in previously reported cases. The experience with our patients suggests that pelvic sonography is a useful noninvasive method both for initial diagnosis of multicystic ovaries and for demonstrating the rapid regression of cysts with thyroid replacement. We also report results of our evaluation of plasma and urinary gonadotropins before and after thyroid treatment and during luteinizing hormone-releasing hormone (LHRH) stimulation and discuss the possible mechanisms responsible for the development of sexual precocity and multicystic ovaries in hypothyroid girls.

METHODS

Baseline serum levels of thyroxine (T_4) and thyroid-stimulating hormone (TSH) and plasma levels of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) and 24-hour urinary concentrations of LH and FSH were obtained before and at variable times after the start of thyroid replacement. Samples for plasma cortisol and serum prolactin were obtained at approximately 8 AM prior to treatment. Twenty-four-hour urine specimens for 17-hydroxycorticosteroids (17-OHCS) and 17-ketosteroids (17-KS) were collected prior to thyroid treatment. Intravenous (IV) three-hour LHRH stimulation tests using 100 μg of LHRH were performed according to the method of Reiter et al[12] on three girls (patients 1 to 3). Plasma samples were obtained at 20-minute intervals before and during the LHRH stimulation. In addition, urine was collected for three-hour periods before, during, and after LHRH infusion for gonadotropin analyses. Patient 4 also underwent a thyrotropin-releasing hormone (TRH) stimulation test, during which she received an IV bolus injection of 200 μg of TRH. Concentrations of LH, FSH, and TSH were measured at 0, 30, 60, 90, 120, 150, and 180 minutes.

Plasma FSH and LH levels were measured by radioimmunoassay (RIA) with use of National Pituitary Agency (NPA) reference standard LER 907 and NPA antisera for LH and FSH. The interassay coefficient of variation for FSH and LH was 8.1 and 7.3, respectively. Urine FSH and LH levels were measured by RIA with use of the World Health Organization Human Menopausal Gonadotropin standard (second IRP-HMG). The T_4, TSH, cortisol, and prolactin concentrations were measured by RIA; 17-OHCS levels were measured by the Glenn-Nelson procedure and 17-KS levels were measured by the Zimmerman reaction. Written informed consents for the LHRH studies were obtained from the patients and/or parents.

Pelvic ultrasound was performed with a gray scale contact scanner. Bone ages were determined according to the standards of Greulich and Pyle.[13]

REPORT OF CASES

CASE 1.—A 12-year 4-month-old girl was found to be hypothyroid six years prior to admission, but received no treatment

in Children With Hypothyroidism

because she was unavailable for follow-up. Thelarche, pubarche, and menarche took place at age 11 years. Her menstrual cycles always were irregular, and she had menorrhagia for 13 days prior to hospitalization. Negligible linear growth had occurred during the preceding three years. Physical examination revealed Tanner stage 2 breasts and pubic hair development and hypertrophied labia minora. A left adnexal mass and adult-sized uterus were palpated on pelvic examination. Her height age was 10 years 3 months and bone age was 10 years. Skull x-ray films revealed an enlarged sella turcica, and pelvic sonography showed bilateral multicystic ovaries, the right measuring 7 × 5 × 4 cm and the left, 4.0 × 4.5 × 3.0 cm. After five weeks of thyroid replacement, the cysts had decreased in size dramatically. Menorrhagia ceased several days after the onset of thyroid treatment, and she has remained amenorrheic during the subsequent eight months.

Case 2.—A 12-year 3-month-old short, premenarcheal girl had experienced no linear growth during the previous two years. Thelarche and adrenarche had occurred at age 11 years. On physical examination, she had axillary sweat and early Tanner stage 2 breasts and pubic hair development. No abdominal masses were palpable. Her height age was 7 years 10 months and bone age was 10 years. Skull x-ray films were normal. On pelvic sonography, she was found to have bilateral multicystic ovaries. The right ovary measured 3 × 2 × 4 cm and the left, 3.5 × 3.5 × 2.0 cm. The largest cyst had a diameter of 2 cm. Repeated sonography after two months of thyroid therapy revealed almost complete resolution of the cysts.

Case 3.—A 16-year 2-month-old girl had grown only 2 cm since age 11. Although menarche occurred at 13 years, she only had six subsequent menstrual periods. She exhibited Tanner stage 2 breasts and pubic hair development. No abdominal masses were palpable. Her height age was 9 years 3 months. Bone age was 11 years, and skull x-ray films were normal. Pelvic sonography demonstrated bilateral multicystic ovaries, the right measuring 2 × 2 × 2 cm

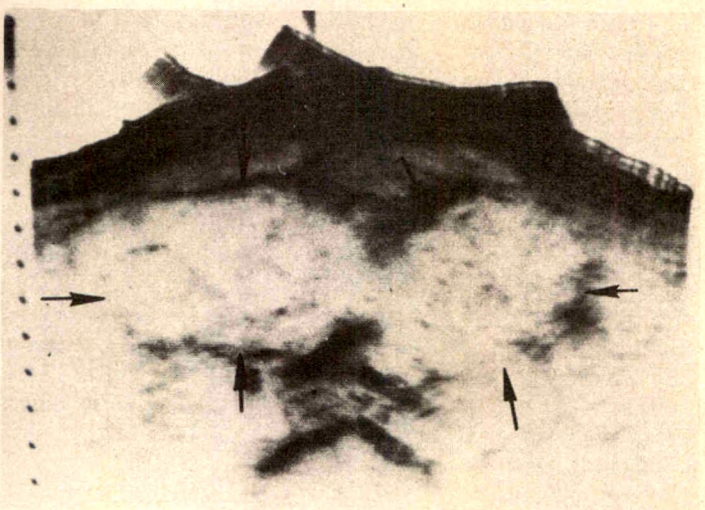

Fig 1.—Pelvic ultrasound of patient 4 prior to thyroid therapy. Arrows outline enlarged ovaries with multiple cysts.

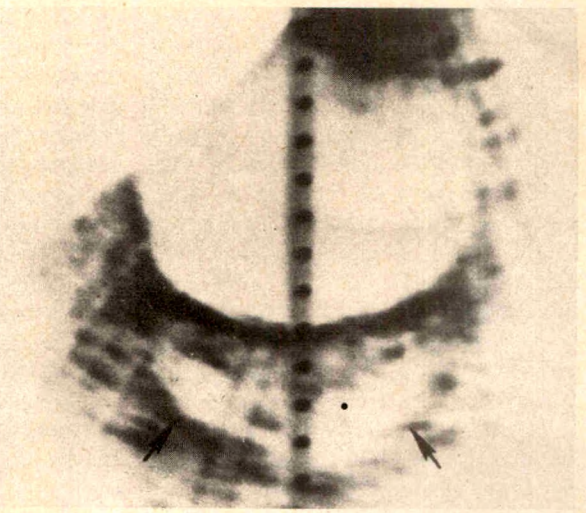

Fig 2.—Repeated pelvic ultrasound of patient 4 after three months of thyroid replacement. Arrows locate smaller ovaries with no cysts present.

and the left, 4.0 × 3.5 × 4.0 cm, with the largest cyst diameter 4 cm. The cysts completely resolved after one month and menses had not yet resumed after six months of thyroid therapy.

CASE 4.—A 14-year 5-month-old girl experienced dramatic deceleration in her linear growth rate at 10 years of age and growth cessation at age 13. Thelarche and adrenarche occurred at age 11 years and menarche occurred at age 14. Subsequent menstrual periods were irregular. Persistent, severe galactorrhea, which was occasionally blood-tinged, began at 14 years. She exhibited Tanner stage 3 breast development, Tanner stage 2 pubic hair, and hypertrophy of her labia minora. There were no palpable abdominal masses. Her height age was 11 years 1 month and bone age was 11 years. Skull x-ray films revealed an enlarged sella turcica, and a computerized tomography scan demonstrated an enlarged pituitary gland without ventricular dilation. Pelvic ultrasound disclosed bilateral multicystic ovaries (Fig 1) measuring 7.0 × 5.5 × 8.0 cm on the right and 4.0 × 5.0 × 5.5 cm on the left. After six months of thyroid therapy, she no longer had galactorrhea and had had no menses. A repeated sonogram after three months of therapy revealed near complete resolution of the ovarian cysts (Fig 2).

RESULTS

Baseline serum T_4, TSH, prolactin, plasma cortisol, plasma, urinary FSH and LH, and urinary 17-KS and 17-OHCS values, as well as post-treatment T_4, TSH, and gonadotropin values are given in Table 1. All four patients had very low serum T_4 and high TSH levels. Baseline plasma LH concentrations were increased in three patients and returned to the normal range following thyroid replacement. All plasma FSH levels were within the normal range. Baseline 24-hour urinary LH and FSH concentrations were normal or low and increased with thyroid therapy. The output of urinary 17-KS and 17-OHCS was low for age. Serum prolactin concentrations were mildly to moderately elevated in three of four patients.

Table 2 summarizes the results of LHRH testing in three patients. Two patients (1 and 4) had no rise in serum or urine gonadotropin values with LHRH stimulation. The baseline plasma LH concentrations were high in patient 1 and normal in patient 4. Patient 3 had elevated baseline LH concentrations and showed a twofold to threefold response to LHRH.

Patient 4 also had a TRH stimulation test; plasma TSH increased from a baseline value of 1,000 μU/mL to a peak concentration of 2,000 μU/mL at 30 minutes. A slight increase in FSH (3.1 mIU/mL to 5.9 mIU/mL) and a minimal rise in LH (4.9 mIU/mL to 5.6 mIU/mL) were noted.

COMMENT

Although sexual precocity is relatively common in children with hypothyroidism, multicystic ovaries have rarely been reported. First described by Silver in 1958,[7] there has been a total of 11 cases reported in the pediatric literature (Table 3). All were identified by discovery of a mass on abdominal or pelvic examination. Five girls had ovarian surgery; three underwent biopsies to rule out tumors,[2,3,7] and two underwent gonadectomy because of ovarian torsion.[8-11] The pathology reports noted cystic follicles with partial to excessive luteinization of the theca interna and generally decreased numbers of primordial follicles. The six other patients were treated conservatively with thyroid replacement, which led to resolution of the ovarian enlargement.

We are describing four additional girls with severe hypothyroidism who had multicystic ovaries confirmed by pelvic sonography. By abdominal examination, a definite mass was palpable in only one of the four. To our knowledge, patient 2 is the first case of a girl with multicystic ovaries and hypothyroidism diagnosed prior to menarche to be reported. With thyroid replacement, all of our patients showed rapid regression of their cysts within one to three months. Interestingly, these patients represent four consecutive cases of severe hypothyroidism referred to our endocrine clinic. Since multicystic ovaries were unsuspected in three of the four patients until discovered by pelvic sonography, this disorder may be much more common than was formerly believed.

The association of hypothyroidism and precocious puberty was first described by Kendle[1] in 1905, but it was not until half a century later that further cases were reported.[2,7,8] Up to 1972, only 23 cases had been recorded,[4] but since that time, it has become apparent that early sexual development is a more frequent occurrence in hypothyroid children than was thought previously. In a review of 54 cases of primary hypothyroidism, Barnes et al[5] found that 58% of the girls and 56% of the boys showed some degree of sexual precocity if sexual maturation was compared with bone age rather than chronologic age.

On the basis of osseous maturation, three of our patients can be considered precocious even though they began pubertal development at an appropriate chronologic age. Features described in the earlier reports were noted in our patients, ie, grossly irregular menses with relatively immature breast and pubic hair development, galactorrhea in one, and labia minora hypertrophy in two. Following thyroxine supplementation, all three had a cessation of menses. The fourth patient, patient 2, could not be considered precocious because her secondary sexual development was appropriate for her bone age. Nevertheless, she had hormonal and ovarian findings that were similar to those of the other three patients.

For the most part, our hormonal results are similar to those previously recorded in children with primary hypothyroidism and sexual precocity.

All have had profound hypothyroidism with high TSH levels. Prolactin concentrations were measured in five previously described patients,[4,6] and all had markedly elevated levels in contrast to the modest increases seen in three of our four subjects. Plasma gonadotropins have been measured in 23 cases.[4-6,14-16] In one series,[15] both LH and FSH levels were increased, with a predominance of FSH. Others[4,6,16] reported higher LH than FSH concentrations. Three of our patients had high plasma LH levels, but the FSH concentration was normal in each.

It is possible that the ovarian cysts seen in hypothyroid girls result from chronic LH stimulation since an association between high LH concentration and cyst formation has been reported. McNatty et al[17] found that cysts occurred in many women whose follicular fluid had increased amounts of LH. Furthermore, elevated LH in the presence of normal FSH has been implicated in the etiology of polycystic ovary disease.[18]

There have been several mechanisms proposed to explain the abnormal sexual maturation in girls with hypothyroidism: (1) an overlap in the pituitary hormonal feedback mechanism resulting in nonspecific hormone release in response to a single target gland deficiency[2]; (2) early maturation of the hypothalamic-pituitary-gonadal axis, such as occurs in idiopathic isosexual precocity; (3) decreased hepatic metabolism of sex steroids, producing a mild elevation of estrogen concentration[3]; (4) enhanced ovarian sensitivity to gonadotropins, as has been suggested from studies in hypothyroid rats[19]; (5) hyperprolactinemia, causing either increased estrogen production or gonadotropin secretion.[4-6] The diversity of proposals indicates the uncertain pathophysiologic features. Exceptions can be raised for each hypothesis.

We noted a discrepancy between baseline serum and urinary gonadotropin levels in our patients. Three of the four girls had elevated basal serum LH values but low to normal concentrations in their urine. In earlier case reports, urinary gonadotropin levels measured by bioassay were not elevated despite the presence of sexual precocity.[2-4,7,11,14,20,21] These results suggest an abnormality in either clearance or metabolism. Since steroids in hypothyroid subjects are known to have prolonged half-lives because of reduced metabolism and clearance,[22] it is possible that these processes, coupled with increased production, account for the elevated plasma LH levels in our patients. This explanation is strengthened by the observation that plasma LH levels fell in three of our four patients following thyroid replacement, and urinary values increased in all, albeit only slightly in two.

Attenuated pituitary responses to LHRH stimulation were seen in two of our three patients. Hemady et al[6] reported similar findings in two hypothyroid patients and attributed the abnormality to tonic stimulation that depleted the pituitary of readily releasable reserves of gonadotropins. It is noteworthy that both of our girls with poor responses to LHRH had enlarged sellas on skull x-ray film and that the girl with a normal response had a normal sella turcica. Hemady et al did not report skull x-ray film findings. It is possible that significant pituitary thyrotroph hyperplasia with physical compression of gonadotrophs occurs before there is diminished gonadotropin response to LHRH.

The precise mechanism that causes ovarian cyst formation and precocious sexual maturation in girls with severe long-standing hypothyroidism is not clear. The frequent occurrence of high plasma LH concentrations suggests that this hormone may have etiologic importance, but the role of the gonadotropins needs further clarification. Our experience indicates that abnormalities of the hypothalamic-pituitary-ovarian axis and multicystic ovaries may be more common than previously recognized. An accurate assessment of the frequency of cystic ovaries in primary hypothyroidism is now possible by use of pelvic ultrasound.

Since this article was submitted for publication, we have seen five additional girls with severe long-standing primary hypothyroidism. Two of the girls had multicystic ovaries detected by pelvic sonography, while the other three did not.

This study was supported by the Human Growth Foundation of Western New York, Buffalo, and the Variety Club of Buffalo, Tent No. 7. Ayerst Laboratories, New York, provided the lutenizing hormone-releasing hormone.

Miriam Link assisted in the preparation of the manuscript and Oleta Denz and Barbara Babcock helped in the metabolic studies.

Small-Intestine Length in Infants and Children

Joseph R. Siebert, MS

• Small-intestine length from ligament of Treitz to ileocecal valve was measured in 183 infants and children ranging up to 15 years of age. Elongation of the intestine was rapid until crown-heel length was 60 cm and remained constant from 100 to 140 cm of body length. When patients were placed into three general diagnostic categories (congenital heart disease, abdominal lesions, and miscellaneous) no significant differences were found. However, several striking instances of abnormally long or short small intestines were encountered.

(*Am J Dis Child* 134:593-595, 1980)

The importance of the length of the small intestine has been recognized by surgeons preparing for resections,[1-7] by radiologists trying to pinpoint lesions in the intestinal tract,[8] and by pathologists desiring to assess the functional status of the digestive system at autopsy.[3,7] However, comprehensive studies of intestinal length in children, and for that matter adults, are relatively scarce.

From the Department of Pathology, Children's Hospital of Pittsburgh. Mr Siebert is now with the Department of Laboratories, Children's Orthopedic Hospital and Medical Center, Seattle.

Reprint requests to Department of Laboratories, Children's Orthopedic Hospital and Medical Center, 4800 Sand Point Way NE, Seattle, WA 98105 (Mr Siebert).

Such investigations, using different approaches, have produced variable data.[1,5,6,8-12] Some reports have given arbitrary statements of normal intestinal lengths while omitting the method by which such data were obtained.[1,2,5]

The most comprehensive portmortem study published to date[8] expressed intestinal length as a ratio of body length. Patient age or weight did not correlate with intestinal length. An association between abnormally long small intestines and congenital heart disease was suggested. In that study, the method of measuring the small intestine was not specified, and it was not stated whether the duodenum was included in the measurements.

The present study was based on a simple method for measuring length of the jejunum and ileum, avoiding stretch artifact. The relationship between small-intestine length and congenital heart disease was investigated, as was the possible effect of other diseases on small-intestine length.

METHODS

Data were collected from an autopsy population of 183 cases from 1972 to 1974. Ages ranged from prematurity (30 weeks' gestation) to 15 years.

At autopsy, the abdominal cavity was gently investigated. A ligature was placed around the small intestine at the duodenal-jejunal suspensory ligament (of Treitz) to mark the beginning of the jejunum. In infants and small children, all thoracoabdominal organs were kept intact during en bloc evisceration. In larger children, the gut was removed after ligating and dividing the jejunum at the ligament of Treitz, and the small bowel was removed by cutting across the mesenteric root from cecum to duodenum. Either method left the mesentery intact with jejunum and ileum, ensuring that the small intestine was not stretched.

After evisceration, most of the mesentery was removed by cutting it along the terminal arcade of the mesenteric vasculature. By leaving this portion of mesentery intact with the small intestine, stretching of the gut was prevented. Agonal intussusceptions were reduced before the bowel was measured. A 3-m length of No. 00 silk suture material previously knotted at 1-m intervals was clamped to the antimesenteric border of the jejunum at the ligament marking the ligament of Treitz. With two forceps, the suture was carefully laid along the small bowel to the ileocecal junction, and the length of the suture was then measured.

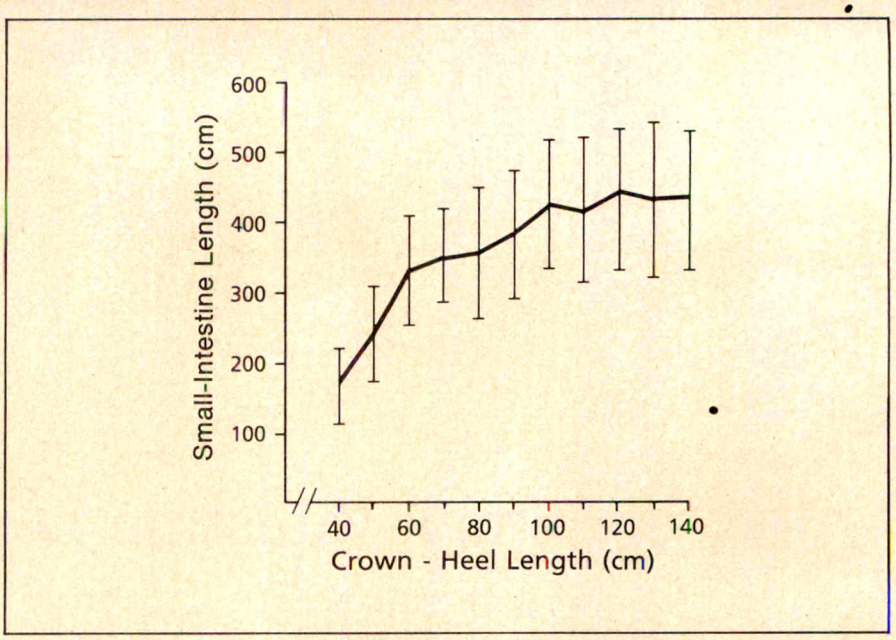
In at least one previous study, patients' ages and body weights did not correlate with small-intestine lengths.[8] The decision to study only the relationship of crown-heel

and small-intestine lengths was therefore made.

The cases were placed into 11 groups, in increments of 10-cm of the crown-heel length (Figure). Mean and SD of small-intestine lengths were calculated for each group. The cases were then placed into one of three diagnostic categories, congenital heart disease, intra-abdominal lesions, or "other." A one-way analysis of variance was performed between and among the categories.[13] The intra-abdominal lesions were itemized, and the mean of small-intestine lengths was calculated for each specific type of lesion.

RESULTS

The data are provided in the Figure and the Table. The Figure graphically details the means and SDs of all cases in the study. Considerable variation within each body-length category is apparent. The data approximate a curve, with the rate of small-intestine elongation decreasing noticeably when the body length reaches 60 cm, the length becoming essentially constant when the body length reaches 100 cm. A one-way analysis of variance of small-intestine lengths in the three categories of congenital heart disease, intra-abdominal lesions, and "others" showed no significant statistical differences within each body-length group. The Table itemizes the small-intestine lengths found in association with intra-abdominal lesions.



Small-intestine length vs crown-heel length, showing means and SDs.

Intra-abdominal Lesions and Small-Intestine Length

Lesion	n	Mean Crown-Heel Length, cm	Mean Small-Intestine Length, cm	Normal Small-Intestine Length, cm*
Atresia of colon	1	35	130	164 ± 54
Necrotizing enterocolitis	4	42	199	164 ± 54
Imperforate anus	1	44	152	164 ± 54
"Prune belly" syndrome	1	44	294	164 ± 54
Hirschsprung's disease, total	1	47	94	239 ± 67
Atresia of ileum	1	49	155	239 ± 67
Omphalocele	2	49	163	239 ± 67
Diaphragmatic hernia	6	50	200	239 ± 67
Isolated malrotation	8	51	248	239 ± 67
Volvulus	1	52	161	239 ± 67
Exstrophy of urinary bladder	1	57	476	328 ± 77
Hepatoblastoma	1	75	308	351 ± 93
Hirschsprung's disease, distal colon	1	94	486	378 ± 90

*Mean ± 1 SD for corresponding crown-heel length group.

COMMENT

Determinations of small-intestine length have been made in both living and dead subjects, but variation between the two groups has been striking. The reported total length of the gastrointestinal tract is 450 cm in the living adult, of which 60% or 270 cm is contributed by the small intestine.[10] Reiquam et al[8] found that the average small-intestine length postmortem in a 160-cm adult was 555 cm, or twice that measured in living subjects. In the study by Reiquam et al and in our study, an intestinal length of about 270 cm was found in neonates. Loss of smooth muscle tone has been the given reason for the apparent postmortem elongation of the intestinal tract.[10] However, the frequent existence of intussusceptions seen at autopsies, especially those of children, has been taken as an indication that some degree of contraction of the small-bowel musculature occurs agonally.[14] It has been shown that stretch artifact of 4% in the adult small intestine and 14% in the large intestine can be produced manually.[15] In dealing with the more delicate pediatric tissues, the danger of stretching the gut during manipulation must be avoided.

It has been suggested that children with congenital heart disease may have an abnormally long small intestine.[8] In 13 instances of abnormally long bowel, defined as a small intestine-body length ratio greater than 7:1, six cases occurred in infants with congenital heart disease, four having involvement of the pulmonary valve. In the present study, no significant differences between mean small-intestine length (grouped by body length) obtained in 65 cases of congenital heart disease and in the remaining 118 children without heart disease were found.

In the present study, two patients with abdominal lesions had severely elongated small intestines. In one case of exstrophy of the urinary bladder, the small-intestine length was 476 cm (body length, 57 cm; expected intestinal length, 328 ± 77 cm). In one case of abdominal musculature deficiency or "prune belly" syndrome, the intestinal length was 294 cm (body length, 44 cm; expected intestinal length, 164 ± 54 cm).

The condition of shortened small intestine has also been examined.[3,7,8] In extreme cases of "congenital short small intestine" or "short gut syndrome," the morphologic features consist of a small-intestine length of 30 to 42 cm and malrotation.[7] The ratio of small-intestine length to body length would then be 1:1 or even less. None of the specimens in the present study were shortened to this degree, and none carried the clinical diagnosis of short-bowel syndrome. In the report by Reiquam et al,[8] of 16 children with small intestine-body length ratios less than 3:1, seven had malrotation and/or omphalocele. It was suggested that a patient with omphalocele and multiple anomalies has a longer small intestine than those without other anomalies.

That suggestion is weakly substantiated by two patients with omphalocele in the present study. The first, a patient with trisomy 18 syndrome, had a body length of 48 cm and an intestinal length of 190 cm, well within 1 SD from the mean. The second, with more minor anomalies (azygous continuation of inferior vena cava and hypoplastic right thumb), had an intestinal length of 136 cm, more than 1 SD less than the mean for his 50-cm body length.

Of the 29 cases involving an intra-abdominal lesion, the most severe shortening was seen in an infant with total aganglionosis or Hirschsprung's disease. This unoperated on infant whose body length was 47 cm had a 94-cm small intestine, far less than the normal range encountered in this study and the normal 5:1 ratio found by Reiquam et al.[8] This finding was in contrast to that of a 6-year-old patient (body length, 94 cm) with a long-standing colostomy for Hirschsprung's disease of the distal colon. The small-intestine length was 486 cm, slightly more than 1 SD greater than the mean for crown-heel length.

One case each of ileal atresia and volvulus had a short small intestine whose length was more than 1 SD lower than the mean. The intestinal lengths of other cases involving intra-abdominal lesions are given in the Table.

Albert W. Dibbins, MD, and Frank E. Sherman, MD, of the Departments of Surgery and Pathology, respectively, Children's Hospital of Pittsburgh, asked questions and gave advice during the early stages of the investigation. J. Bruce Beckwith, MD, Department of Laboratories, Children's Orthopedic Hospital and Medical Center, Seattle, provided advice in the final stages of the study.

Intravenous Aminophylline Therapy for Asthma

A Comparison of Two Methods of Administration in Children

Paul Goldberg, MD; Fred Leffert, MD; Mario Gonzalez, PhD; Larry Gogenola, MS; Gary O. Zerbe, PhD

• Eleven asthmatic children were given intravenous aminophylline by two methods of administration: a 6 mg/kg loading dose followed by a 1.1 mg/kg/hr continuous infusion, or a bolus of 4 mg/kg given every four hours. Expiratory flow rates (forced expiratory volume at 1 s and expiratory flow at 50% of vital capacity) were recorded at intervals for 24 hours with each regimen. Although the intermittent administration of aminophylline produced a substantial improvement, there was a significantly greater pulmonary response to continuous infusion.

(*Am J Dis Child* 134:596-599, 1980)

The use of intravenous (IV) aminophylline in the treatment of asthma has become widely accepted in contemporary pediatric practice. Although it appears to be an effective agent for treatment of acute exacerbations of asthma,[1] an optimal method of administration has not been defined. Currently, two approaches are in use: injection of a bolus dose at regular intervals, or injection of a loading dose followed by constant infusion of the drug. This study compares the effects of these two methods in a group of asthmatic children.

Accepted for publication Dec 10, 1979.

SUBJECTS AND METHODS

The subjects were 11 children (six girls and five boys) between the ages of 7 and 15 years. All subjects met the criteria for reversible obstructive airway disease of the American Thoracic Society.[2] All were inpatients at the National Jewish Hospital, Denver, for treatment of perennial asthma, and had been shown to require regular daily use of oral bronchodilators for maintenance of good pulmonary function. None had received corticosteroids for at least two weeks prior to the study. Informed consent was obtained from children and their parents.

Each subject was studied on two days, with a one-week interval between study days. Studies were conducted in the pediatric clinical research unit, and began at 8 AM on each study day. All medication was withheld for at least 12 hours before beginning each trial. A child was admitted to the study only if his baseline expiratory flow rates (1-s forced expiratory volume [FEV_1] and forced expiratory flow at 50% of vital capacity [FEF_{50}]) were less than 80% of predicted, and (for the second day) if flow rates were within 20% of baseline rates for the first day. Children experiencing respiratory distress and requiring additional medication were discharged from the study. After baseline pulmonary function and serum theophylline measurements were obtained, each subject was randomly assigned to a treatment protocol, with the other protocol used on the second study day.

Continuous infusion consisted of a loading dose of 6 mg/kg of aminophylline, which was given in a 25-mL volume during five minutes by infusion pump, followed by a continuous infusion of 1.1 mg/kg/hr by the same apparatus. The infusion was continued for 24 hours. Intermittent administration consisted of a dose of 4 mg/kg of aminophylline in a 25-mL volume given during five minutes by infusion pump. This was repeated every four hours for 24 hours (six doses). The protocol for continuous infusion followed the recommendations of Piafsky and Ogilvie,[3] while the intermittent administration regimen has been the customary approach at National Jewish Hospital for several years.

Subjects had catheters placed in peripheral veins in both arms, so that drug administration and blood sampling for serum theophylline levels were accomplished through separate systems. Children were observed by nurses during the entire study period, and pulse, blood pressure, auscultation of the chest, and inquiries as to dyspnea, abdominal distress, or CNS stimulation were recorded every four hours. Blood specimens were obtained for measurement of serum theophylline concentration, and spirometry was performed immediately before beginning aminophylline infusion, and 1, 4, 8, 12, and 24 hours afterward. For the intermittent administration protocol, these measurements (except at one hour) were obtained immediately before the next dose, and so represent trough levels of theophylline.

Forced vital capacity maneuvers were performed with a wedge spirometer, with recording of maximal expiratory flow-volume curves on an X-Y plotter. The better of two efforts was used for determination of the FEV_1 and the FEF_{50}.

Blood samples for serum theophylline measurement were obtained from a catheter placed in a peripheral vein. Serum was separated and frozen for later analysis by high-pressure liquid chromatography. The serum clearance rate was calculated for each patient from the continuous infusion data. This calculation consisted of dividing the maintenance rate of infusion by the mean steady-state serum concentration (average of the values at 4, 8, 12, and 24 hours).

The statistical tests employed for evaluation of the pulmonary function data were introduced by Zerbe and Walker[4] for the

purpose of comparing mean growth curves. More recently, Zerbe[5,6] has refined these techniques and indicated their applicability to dose-response and time-response curves. They are particularly well suited to the problem of comparing pulmonary function curves during an interval of time without the need for separate t tests at each point within the interval. They are also nonparametric tests requiring no distribution assumptions, particularly appealing when the end point is a percent change from baseline.

RESULTS

The pulmonary responses to the two methods of treatment are shown in Fig 1 to 5 and in Table 1. Figures 1 to 4 display group data, while Fig 5 shows the responses of individual subjects.

Figure 1 displays the mean FEV_1 response curves. The FEV_1 response to continuous administration was greater than that for intermittent dosage, but not significantly so

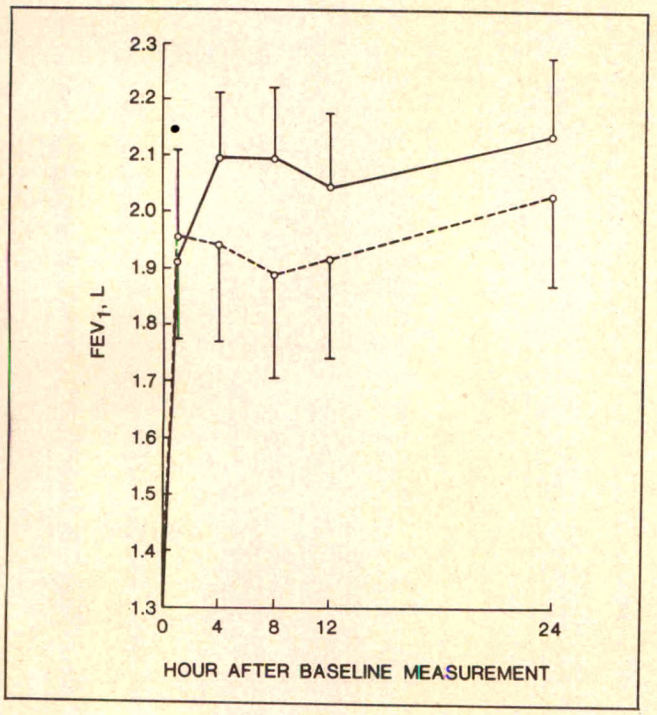

Fig 1.—Mean 1-s forced expiratory volume (FEV_1) responses to continuous (solid line) and intermittent (broken line) treatment ±1 SEM.

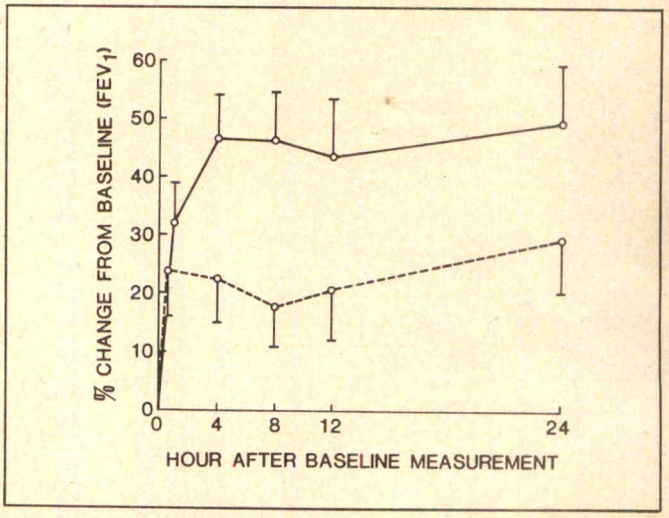

Fig 2.—Mean percent change in 1-s forced expiratory volume (FEV_1) for continuous (solid line) and intermittent (broken line) treatment ±1 SEM.

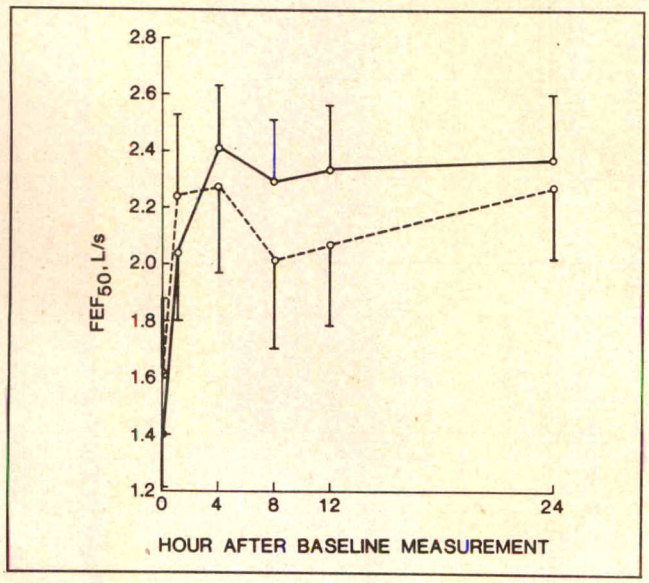

Fig 3.—Mean forced expiratory flow at 50% of vital capacity (FEF_{50}) responses to continuous (solid line) and intermittent (broken line) treatment ±1 SEM.

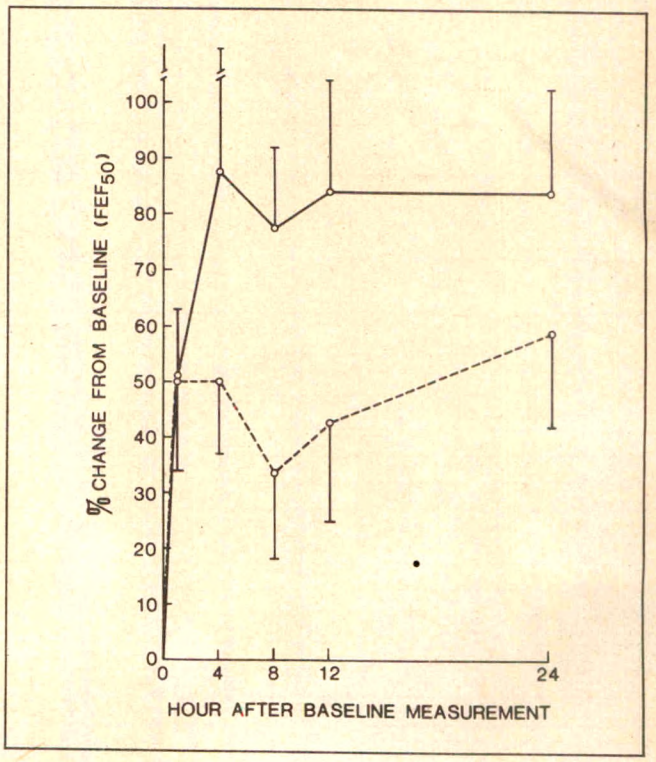

Fig 4.—Mean percent change in forced expiratory flow at 50% of vital capacity (FEF_{50}) for continuous (solid line) and intermittent (broken line) treatment ±1 SEM.

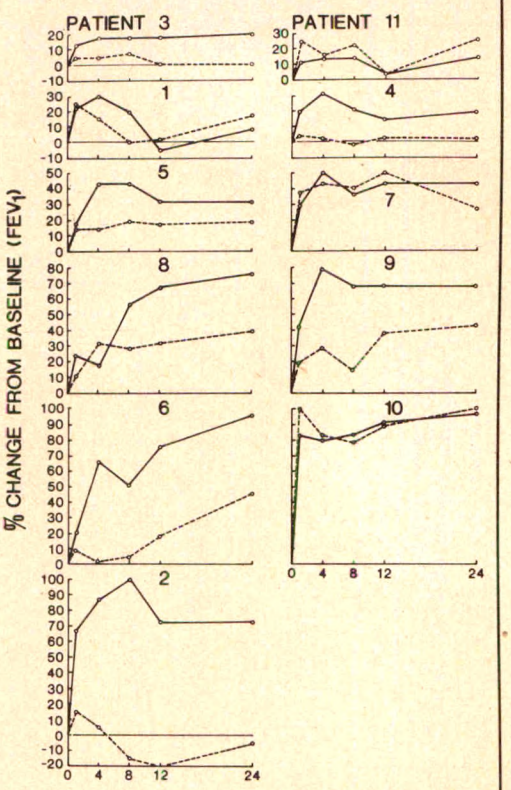

Fig 5.—Responses of individual subjects (percent change in 1-s forced expiratory volume [FEV_1]) to continuous (solid line) and intermittent (broken line) treatment.

(P = .1). Although the 0.14-L difference between the baselines for the two groups was also nonsignificant (P = .08), the comparison was made again after adjusting for the baselines. Figure 2 displays mean percent change from baseline FEV_1 response curves. After this adjustment, the response curve for continuous administration is significantly elevated over that for intermittent treatment (P = .01) during the 24-hour period.

Similarly, Fig 3 and 4 display FEF_{50} response curves, and mean percent change from baseline FEF_{50} response curves, respectively. On the absolute scale, the continuous and intermittent response curves are not significantly different (P = .20), nor is the difference between baseline values (P = .08). However, when viewed as percent change from baseline, the response curve for continuous administration is significantly elevated over that for intermittent dosage (P = .02).

Figure 5 shows the responses of individual children in terms of percent change in FEV_1. There was a great deal of variability among subjects,

with a very marked superiority of continuous over intermittent treatment in some children (particularly subjects 2, 6, and 9), while others showed little difference in their responses (eg, subjects 7 and 10). No subject showed a greater response to intermittent than to continuous treatment.

Six children had wheezing at the beginning of both study days, which resolved after treatment began. No children had objective (pulse, blood pressure) or subjective (CNS or gastrointestinal) findings suggesting theophylline toxicity while on either regimen. Pharmacokinetic data are summarized in Table 2.

COMMENT

Interpretation of these data requires consideration of several factors that may have influenced the results of the study. The subjects, although experiencing active disease requiring bronchodilator treatment, were not suffering from status asthmaticus. The study of patients with status asthmaticus would have introduced several difficulties, including lack of control of prestudy medication, the need for concomitant use of sympathomimetic drugs, and difficulty in obtaining satisfactory spirograms in distressed children. We therefore chose to compare the bronchodilating efficacies of these regimens in a more controlled setting than is possible in the actual clinical situation.

It will also be noted that the study design appears to favor the demonstration of greater efficacy for the continuous infusion method. Spirometry was performed when the serum theophylline concentration was at a trough level during the intermittent regimen. Also, the total amount of aminophylline given during the continuous infusion was greater—6 vs 4 mg/kg at the onset, and a total dose of 32.4 vs 24.0 mg/kg during the 24 hours. The 4 mg/kg dose was selected because it represented the customary therapy at our institution, and it was this traditional approach that we wished to compare with the newer technique. Pulmonary function measurements were made at trough levels for two reasons. Since serum theophylline concentration appears to correlate with therapeutic efficacy only insofar as it is a reflection of tissue level of the drug,[7] selection of optimal time for sampling becomes complicated, since a sample taken too soon may give a spuriously high level during the distributive phase. The trough level measurement also reflects our feeling that the lowest level to which pulmonary function is allowed to fall during treatment may be the most clinically relevant consideration.

Although medication had been withheld for at least 12 hours prior to the study days, all subjects had theophylline detected in the baseline serum sample (Table 1). Although these levels were very low (mean of 3.0 μg/mL for intermittent vs 4.2 μg/mL for continuous administration), it is possible that this difference also contributed to the better response shown in the continuous infusion group.

After taking all of these factors into account, it was somewhat surprising that, excepting subjects 2, 6, and 9, the difference in response between the two methods was not impressive for most of the children, even though the inclusion of these three subjects gives a statistically significant difference for the mean group responses.

The finding of a wide range of clearance rates for theophylline in this group of children is in agreement with the results of more extensive pharmacokinetic studies.[8] Following the recommendations of Piafsky and Ogilvie[3] for aminophylline infusion led to the maintenance of serum levels in the "therapeutic range" (10 to 20 μg/mL) in all subjects. However, it should be noted that if their higher dose regimen (9 mg/kg loading followed by 1.65 mg/kg/hr) had been used, several subjects would have attained serum levels well over 20 μg/mL. We considered the possibility that serum clearance rate might be a major determinant of whether a subject gave similar or different responses to the two treatment protocols, but were unable to demonstrate such a relationship. For instance, subjects 2 and 3 had very similar clearance rates, but strikingly different pulmonary response patterns.

Although intermittent injection of aminophylline at 4 mg/kg was less efficacious than continuous administration in improving pulmonary function, it did give a clinically significant response (≥ 20% increase in FEV_1). Therefore, it appears to be an effective technique for asthma therapy, although perhaps no longer the method of choice. A problem inherent in continuous administration is the need for reliable maintenance of the infusion during long periods of time, with regular monitoring of the amount of drug infused. The serum theophylline level of 23.3 μg/mL noted in subject 6 was most likely due to human or mechanical error in the maintenance of a steady infusion rate. In situations where adequate personnel and equipment are not available, intermittent administration may represent a simple safe alternative.

The results of this study suggest that use of a loading dose followed by a continuous infusion of aminophylline will, on the average, give a better pulmonary response than intermittent injection of the drug, at least at the dosages used herein. The infusion technique therefore appears to be the method of choice for IV aminophylline therapy. Intermittent administration may be a useful alternative approach in clinical settings in which the infusion technique cannot be safely and reliably implemented.

You can help the ADD* child with Cylert
(pemoline)

Day-long behavior therapy without dosing problems at school

Impressive all-day control.

Cylert works extremely well, given an adequate period of trial. Single daily doses are as effective for behavior control as multiple doses of methylphenidate or amphetamines. Blood levels are well sustained, without necessity for multidose administration.

No troublesome midday dose.

Cylert avoids problems of taking a drug at school. No involvement of school personnel. No peer teasing about noon-time dosing. The parents manage all medication, and the child carries no drugs. (And note that Cylert is Schedule IV, not II.)

Cylert® (pemoline) C IV

18.75, 37.5, 75 mg tablets; 37.5 mg chewables

Just once a day. At home.

*ADD: Attention Deficit Disorder (formerly called MBD, Minimal Brain Dysfunction), or the Hyperkinetic Syndrome. Please see next page for Brief Summary.

ABBOTT

9083319

Cylert® (pemoline)

DESCRIPTION: CYLERT (pemoline) is a central nervous system stimulant. Pemoline is structurally dissimilar to the amphetamines and methylphenidate.

It is an oxazolidine compound and is chemically identified as 2-amino-5-phenyl-2-oxazolin-4-one.

Pemoline is a white, tasteless, odorless powder, relatively insoluble (less than 1 mg./ml.) in water, chloroform, ether, acetone, and benzene; its solubility in 95% ethyl alcohol is 2.2 mg./ml.

CYLERT (pemoline) is supplied as tablets for oral administration.

CLINICAL PHARMACOLOGY: CYLERT (pemoline) has a pharmacological activity similar to that of other known central nervous system stimulants; however, it has minimal sympathomimetic effects. Although studies indicate that pemoline may act in animals through dopaminergic mechanisms, the exact mechanism and site of action of the drug in man is not known.

There is neither specific evidence which clearly establishes the mechanism whereby CYLERT produces its mental and behavioral effects in children, nor conclusive evidence regarding how these effects relate to the condition of the central nervous system.

The serum half-life of pemoline is approximately 12 hours. Peak serum levels of the drug occur within 2 to 4 hours after ingestion of a single dose. Multiple dose studies in adults at several dose levels indicate that steady state is reached in approximately 2 to 3 days.

Metabolites of pemoline include pemoline conjugate, pemoline dione, mandelic acid, and unidentified polar compounds. CYLERT is excreted primarily by the kidneys; approximately 75% of an oral dose is recovered in the urine within 24 hours. Approximately 43% of pemoline is excreted unchanged.

CYLERT (pemoline) has a gradual onset of action. Using the recommended schedule of dosage titration, significant clinical benefit may not be evident until the third or fourth week of drug administration.

INDICATIONS: CYLERT is indicated as an integral part of a total treatment program which typically includes other remedial measures (psychological, educational, social) for a stabilizing effect in children with a behavioral syndrome characterized by the following group of developmentally inappropriate symptoms: moderate to severe distractibility, short attention span, hyperactivity, emotional lability, and impulsivity. The diagnosis of this syndrome should not be made with finality when these symptoms are only of comparatively recent origin. Nonlocalizing (soft) neurological signs, learning disability, and abnormal EEG may or may not be present, and a diagnosis of central nervous system dysfunction may or may not be warranted.

Attention Deficit Disorder and Hyperkinetic Syndrome are among the terms being used to describe the above signs and symptoms. In the past, a variety of terms has been associated with these signs and symptoms, including: Minimal Brain Dysfunction, Hyperkinetic Reaction of Childhood, Hyperkinetic Syndrome, Hyperactive Child Syndrome, Minimal Brain Damage, Minimal Cerebral Dysfunction, and Minor Cerebral Dysfunction.

CONTRAINDICATIONS: CYLERT (pemoline) is contraindicated in patients with known hypersensitivity or idiosyncrasy to the drug. (See ADVERSE REACTIONS.)

WARNINGS: CYLERT is not recommended for children less than 6 years of age since its safety and efficacy in this age group have not been established.

Clinical experience suggests that in psychotic children, administration of CYLERT may exacerbate symptoms of behavior disturbance and thought disorder.

Data are inadequate to determine whether chronic administration of CYLERT may be associated with growth inhibition; therefore, growth should be monitored during treatment.

PRECAUTIONS: Drug treatment is not indicated in all cases of the behavioral syndrome characterized by moderate to severe distractibility, short attention span, hyperactivity, emotional lability and impulsivity. It should be considered only in light of the complete history and evaluation of the child. The decision to prescribe CYLERT should depend on the physician's assessment of the chronicity and severity of the child's symptoms and their appropriateness for his/her age. Prescription should not depend solely on the presence of one or more of the behavioral characteristics.

When these symptoms are associated with acute stress reactions, treatment with CYLERT is usually not indicated.

Long-term effects of CYLERT in children have not been well established.

Liver function tests should be performed prior to and periodically during therapy with CYLERT. The drug should be discontinued if abnormalities are revealed and confirmed by follow-up tests. (See ADVERSE REACTIONS regarding reports of abnormal liver function tests and jaundice.)

CYLERT should be administered with caution to patients with significantly impaired hepatic or renal function.

The interaction of CYLERT with other drugs has not been studied in humans. Patients who are receiving CYLERT concurrently with other drugs, especially drugs with CNS activity, should be monitored carefully.

CYLERT failed to demonstrate a potential for self-administration in primates. However, the pharmacologic similarity of pemoline to other psychostimulants with known dependence liability suggests that psychological and/or physical dependence might also occur with CYLERT. There have been isolated reports of transient psychotic symptoms occurring in adults following the long-term misuse of excessive oral doses of pemoline. CYLERT should be given with caution to emotionally unstable patients who may increase the dosage on their own initiative.

Usage during Pregnancy and Lactation: The safety of CYLERT (pemoline) for use during pregnancy and lactation has not been established.

Studies in rats have shown an increased incidence of stillbirths and cannibalization when pemoline was administered at a dose of 37.5 mg./kg./day. Postnatal survival of offspring was reduced at doses of 18.75 and 37.5 mg./kg./day.

ADVERSE REACTIONS: Insomnia is the most frequently reported side effect of CYLERT; it usually occurs early in therapy, prior to an optimum therapeutic response. In the majority of cases it is transient in nature or responds to a reduction in dosage.

Anorexia with weight loss may occur during the first weeks of therapy. In the majority of cases it is transient in nature; weight gain usually resumes within three to six months.

Stomach ache, skin rashes, increased irritability, mild depression, nausea, dizziness, headache, drowsiness, and hallucinations have been reported.

Elevations of SGOT, SGPT, and serum LDH have occurred in patients taking CYLERT, usually after several months of therapy. These effects appear to be reversible upon withdrawal of the drug, and are thought to be manifestations of a delayed hypersensitivity reaction. There have also been a few reports of jaundice occurring in patients taking CYLERT; a causal relationship between the drug and this clinical finding has not been established.

The following CNS effects have been reported with the use of CYLERT: dyskinetic movements of the tongue, lips, face and extremities, nystagmus and nystagmoid eye movements, and convulsive seizures. A definite causal relationship between CYLERT and these reactions has not been established.

Mild adverse reactions appearing early during the course of treatment with CYLERT often remit with continuing therapy. If adverse reactions are of a significant or protracted nature, dosage should be reduced or the drug discontinued.

OVERDOSAGE: Signs and symptoms of acute CYLERT overdosage may include agitation, restlessness, hallucinations, dyskinetic movements and tachycardia. The treatment for an acute overdosage of pemoline is essentially the same as that for an overdosage of any CNS stimulant. Management is primarily symptomatic and may include induction of emesis or gastric lavage, sedation, and other appropriate supportive measures.

Results of studies in dogs indicate that extracorporeal hemodialysis may be useful in the management of CYLERT overdosage; forced diuresis and peritoneal dialysis appear to be of little value.

DOSAGE AND ADMINISTRATION: CYLERT (pemoline) is administered as a single oral dose each morning. The recommended starting dose is 37.5 mg./day. This daily dose should be gradually increased by 18.75 mg. at one week intervals until the desired clinical response is obtained. The effective daily dose for most patients will range from 56.25 to 75 mg. The maximum recommended daily dose of pemoline is 112.5 mg.

Clinical improvement with CYLERT is gradual. Using the recommended schedule of dosage titration, significant benefit may not be evident until the third or fourth week of drug administration.

Where possible, drug administration should be interrupted occasionally to determine if there is a recurrence of behavioral symptoms sufficient to require continued therapy.

MEDICAL DIRECTOR
Children's Hospital

The highly respected La Rabida-University of Chicago Institute and the La Rabida Children's Hospital and Research Center is seeking an outstanding pediatrician as Medical Director of this specialized hospital for the care of infants and children with a variety of chronic medical diseases. The majority of the admissions to the 77 bed inpatient facility and visits to the ambulatory care section (about 9000 visits per year) are for immunologic diseases (primarily pulmonary, rheumatologic and renal). The hospital also provides rehabilitative services for the physically disabled child, regardless of etiology. The hospital is a completely integrated component of the Department of Pediatrics of the Pritzker School of Medicine of the University of Chicago. Training in pediatrics for housestaff and medical students includes rotation through La Rabida. Clinical care is provided by 9 full-time faculty pediatricians and a support staff of psychologists, social workers, and physical therapists. The Research Center has a faculty of 6 basic immunologists, 18 graduate students and a laboratory support staff of 24.

The medical director will be responsible for development and organization of teaching and clinical care in the hospital and for supervision of clinical research programs.

A regular academic appointment of appropriate rank will be made in the Department of Pediatrics of the University of Chicago, an equal opportunity employer.

La Rabida is on the shore of Lake Michigan in a park 2 miles from the University of Chicago campus; a shuttle bus operates between La Rabida and the University of Chicago.

Please send suggestions for candidates and/or CV and names of three references to: The Search Committee, LaRabida-University of Chicago Institute East 65th Street at Lake Michigan, Chicago, Illinois 60649

For Teenagers with learning problems . . . a beautiful idea in a lovely setting

Riverview provides a warm, supportive environment amid the natural beauty of Cape Cod. Each year, we accept 100 boys and girls ages 13 to 18 with diagnosed perceptual or intellectual learning disabilities. For each student, Riverview's skilled staff creates an individualized program designed to offer a variety of instruction and experiences to strengthen skills, build confidence and improve the student's self-image. Our goal is for each student upon leaving to be within the range of his potential, a wholesome, realistic, mature individual. High School Diploma available. In addition to the traditional program, individual emphasis is given to counseling, physical education, speech therapy, reading/language therapy and mathematics plus a wide choice of pre-vocational and other elective skills. Riverview is private, non-profit and approved by education departments of several states.

For information, contact: Admissions K

Riverview School
East Sandwich, MA 02537
Tel: (617) 888-0489

Riverview admits students of any race, color, national or ethnic origin.

Review

Acute Febrile Mucocutaneous Lymph Node Syndrome

Richard Yanagihara, MD, James K. Todd, MD

More than a decade ago, Tomisaku Kawasaki, a Japanese pediatrician, described an acute exanthematous disease characterized by persistent fever, mucous membrane hyperemia, cervical lymph node enlargement, and periungal desquamation in 50 infants and children who had been seen during the preceding six-year period at the Japan Red Cross Medical Center in Tokyo.[1] Individually the clinical and laboratory features seemed not unlike those of other mucocutaneous syndromes and exanthematous illnesses of childhood, but Kawasaki decided that the constellation of findings was distinctive and constituted a hitherto undescribed clinical entity. The disease was designated mucocutaneous lymph node syndrome (MCLS).[1]

After this description, numerous cases were reported throughout Japan, and in 1970 the Research Committee of MCLS, supported by the Ministry of Health and Welfare of the Japanese government, was organized. The primary purpose of this group was to conduct and to coordinate investigations involving the etiology and the clinical, pathological, and epidemiological features of the disease. Much has since been learned about this syndrome, but there remain major gaps in our understanding about its etiology, pathogenesis, natural history, and treatment.

In recent years MCLS has been the subject of editorials,[2-6] reviews,[7-10] and symposia.[11-12] In 1976, the MCLS study group adopted the eponym Kawasaki's disease in place of the acronym MCLS, thus accepting it as a nosological entity. For some, however, there still remain uncertainties about whether this symptom-complex actually constitutes a novel, discrete clinicopathologic entity.[13-17] Does the designation MCLS denote a heterogeneous population of patients with a variety of previously described infectious or noninfectious illnesses characterized by mucocutaneous manifestations, or does it truly define a homogeneous population of patients with a distinct, hitherto undescribed clinical illness? What is the relationship between this syndrome and other mucocutaneous and vascular disorders, particularly infantile polyarteritis nodosa (IPN)? More specifically, are the clinical or histological features of MCLS sufficiently distinctive to differentiate them from those of IPN? Finally, would it be more appropriate to refer to this aggregate of signs and symptoms as a syndrome or as a disease? We will review the available data in an attempt to answer some of these questions and to determine the position MCLS occupies in relation to other acute febrile mucocutaneous syndromes.

CLINICAL FEATURES

The diagnostic criteria established by the MCLS study group were based on Kawasaki's original detailed description.[1] They are as follows: (1) fever of five or more days; (2) bilateral congestion of the ocular conjunctivae; (3) changes of the mucous membranes of the oral cavity, including erythema, dryness, and fissuring of lips; erythema of the tongue and prominence of the papillae; diffuse reddening of the oropharyngeal mucosa; (4) changes of the peripheral extremities, including reddening and indurative edema of the hands and feet, and membranous periungal desquamation; (5) polymorphous exanthem; (6) acute nonsuppurative swelling of the cervical lymph nodes. The presence of five of these six principal criteria, or, more

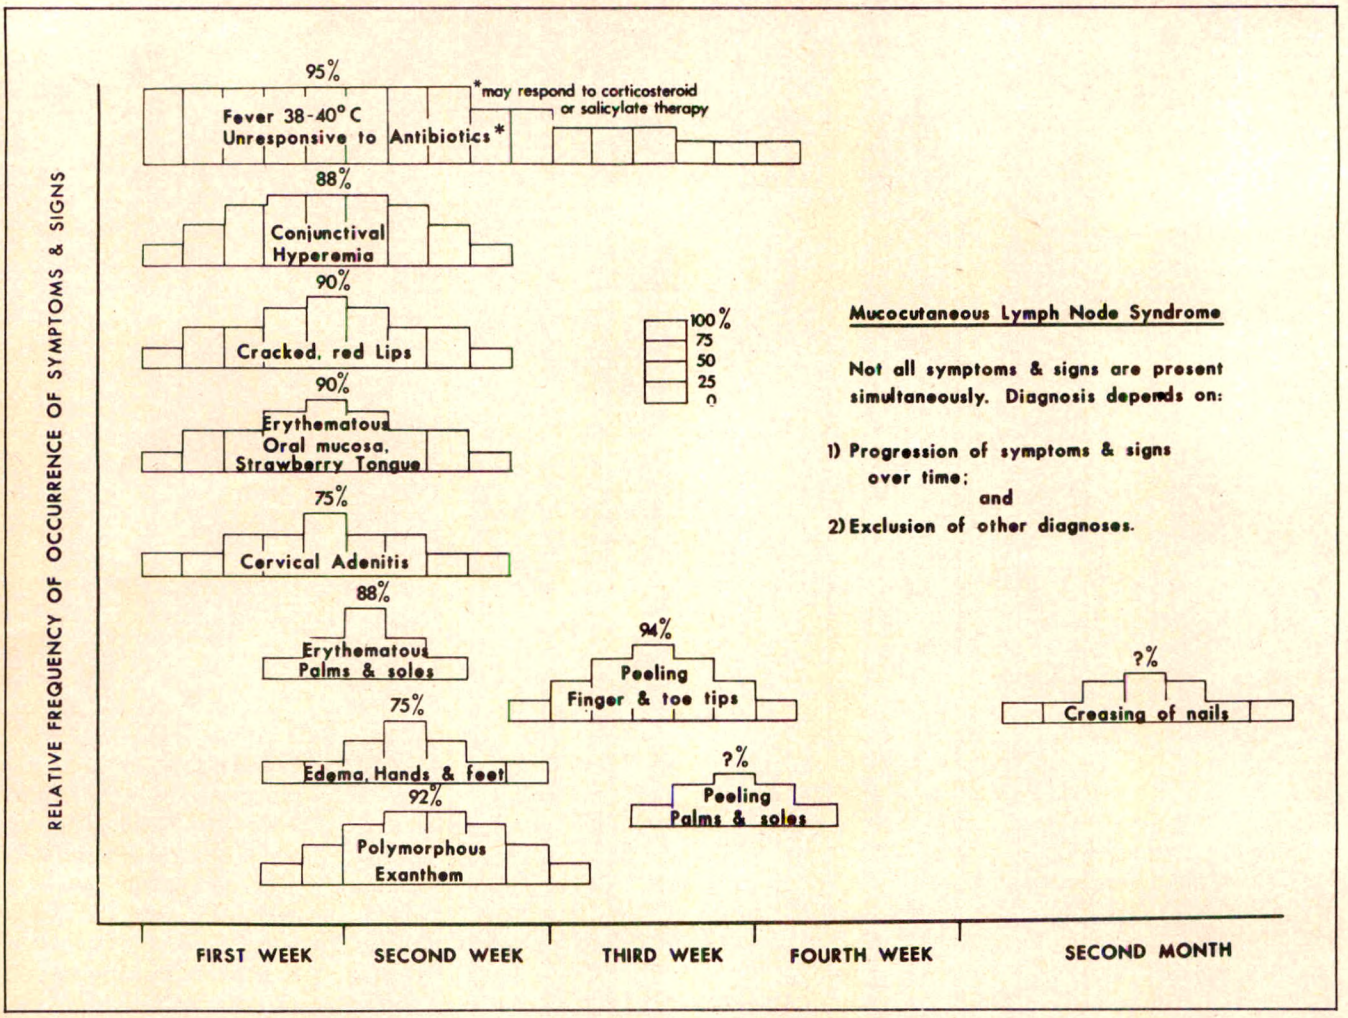

Fig 1.—Clinical manifestations of mucocutaneous lymph node syndrome (percentages from Kawasaki et al[23]).

appropriately, the presence of prolonged fever and four of the remaining five criteria, in the absence of evidence implicating other well-known diseases, is required to establish the diagnosis of MCLS.

According to the case definition then, MCLS is strictly a clinical diagnosis and further it is a diagnosis of exclusion. The symptom-complex evolves over time such that all of the clinical features are not apparent simultaneously (Fig 1).

Mucocutaneous lymph node syndrome is a disease of infants and young children. The age of peak incidence is nine to 12 months in Japan[18] and about 3 years in the United States.[9,19] There is a slight but definite male predominance.[9,18,19]

Generally affected patients appear mildly to moderately ill. Fever, with temperatures ranging from 38.5 to 40.5 °C, is usually the most prominent symptom and is often the reason for hospitalization. The pattern of pyrexia is usually hectic and is totally unresponsive to antibiotic therapy. In most cases, fever persists for eight to 18 days, although prolonged courses of up to five weeks have been reported.[20] It is the height and persistence of fever beyond the usual three- to five-day duration expected for most self-limited viral illnesses in the young child that may first suggest the possibility of MCLS to the clinician.

Shortly after the onset of fever, bilateral congestion of the ocular conjunctivae develops. There is no suppuration or pseudomembrane formation, chemosis, or keratitis. This may be accompanied by diffuse and marked reddening of the lips and the oropharyngeal mucosa, without aphthous ulcerations or hemorrhagic bullae. The vermilion borders of the lips are frequently dry and fissured. Prominent lingual papillae ("strawberry tongue") may also be observed.

In the later half of the first week of illness, marked erythema of the palms and soles and brawny, nonpitting, indurative edema of the hands and feet may develop. Often, an erythematous, macular rash appears, originating frequently on the extensor surfaces of the arms and legs and progressing centripetally. The individual macules or maculopapules enlarge rapidly and frequently become coalescent. The cutaneous eruption is characteristically polymorphous and can be primarily morbilliform (maculopapular), scarlatiniform, or multiform in appearance. Typical iris or target

lesions are sometimes reported,[21,22] but crusts, vesicles, or bullae are not seen and pruritus is distinctly uncommon. The exanthem usually fades within a week, but occasionally may persist or recur.

During the later part of the second and into the third week of illness—usually after the resolution of fever—an unusual membranous desquamation begins in the subungal and periungal regions of the fingers and toes. This finding is especially but not exclusively characteristic of MCLS. Exfoliation is usually minimal or absent in other anatomical sites. Late in the convalescent phase (one to two months) transverse grooves or furrows may develop across the nailbed.[1,23]

Nonpurulent, often unilateral, cervical lymph node enlargement (1.5 cm or more in diameter) is noted commonly at the time of initial presentation or thereafter. Cervical lymphadenopathy can be of such marked degree that retropharyngeal or peritonsillar abscess may be suspected.[24] The mass diminishes in size usually at the time of defervescence. Generalized lymphadenopathy does not occur.

In addition to the six cardinal criteria, other clinical features, such as diarrhea, arthralgia and arthritis, meatitis, tympanitis, photophobia, meningeal irritation, and pneumonia, are often noted during the acute stage of illness. Diarrheal stools are nonbloody and usually nonmucoid. Either arthralgia or frank arthritis with erythema, swelling, warmth, pain, and decreased range of motion may be a prominent feature.[21,23,25-28] Large joints, particularly elbows, wrists, knees, and ankles, are more frequently involved, and oligoarticular involvement is usual.

Meatal inflammation, as evidenced by pyuria on clean-voided urine specimens, is also a common finding (see "Laboratory Findings"). Meatal ulcers occur rarely.

Other findings, such as hydrops of the gallbladder,[29,30] convulsions,[31] encephalopathy,[21,31] jaundice,[23] pleural or pericardial effusions,[32] have been reported but are uncommon.

Probably the most alarming feature of MCLS is the cardiac and coronary arterial involvement. Its actual incidence is unknown. Arrhythmia, myocarditis, pericarditis, congestive heart failure, and myocardial ischemia and infarction have all been reported. Cardiac signs (eg, shock, arrhythmia, distant heart sounds, gallop rhythm) may appear as early as the first week of illness or during prolonged convalescence. While the outcome is generally favorable, approximately 1.5% of children die[18]; deaths usually occur within two months of the onset of illness,[33,34] but may occur years later.[35,36]

EPIDEMIOLOGY

Since the initial description by Kawasaki[1] and the publication of his findings in the English language,[23] there has been a profusion of case reports from many countries. The first cases to be reported outside Japan were from South Korea[37] and Hawaii.[38] The syndrome has since been recognized in Canada,[35,39,40] Mexico,[9] Hungary,[28] Switzerland,[41] West Germany,[42] England,[43-47] the Netherlands,[13,14] India,[26] Kuwait,[27] the Phillipines,[9] Australia,[48] Spain,[9] France,[9] Jamaica,[9] Italy,[49] Greece,[50] Sweden,[51] Turkey,[52] Scotland,[53] Belgium,[54,55] and the continental United States.*

While the Center for Disease Control (CDC) has been gathering information about cases of MCLS occurring in the United States since 1975, most of our present knowledge about the epidemiology of this syndrome comes from the Japanese national surveys. Nationwide retrospective surveys have been conducted by the MCLS study group biennially beginning in 1970.[18,68] Questionnaires and the diagnostic guidelines for MCLS were sent to the pediatric departments of all hospitals with more than 100 patient beds (1,688 hospitals). The response rate was about 40% to 60% for each survey. Data from the 1978 survey are presently being tabulated. Preliminary analysis indicates that the incidence of MCLS has continued to increase and has reached nearly epidemic proportions. About 18,000 cases (15,435 definite and 2,428 probable) have been registered in Japan since the first nationwide survey (I. Shigematsu, MD, verbal communication, 1979). This represents an annual incidence of approximately 2,700 cases in recent years.

It is still uncertain whether the findings of the Japanese epidemiological investigations are applicable to the United States or to other countries. However, recent analysis of the more than 200 MCLS cases submitted to the CDC[9,19] has revealed several epidemiological similarities between the Japanese and American cases. There appears to be no definite seasonal pattern (with the possible exception of a slightly higher incidence during the warmer months in Japan) or geographical limitation. Cases have been registered in all 46 prefectures of Japan,[18] and the CDC has learned of cases from the District of Columbia, Puerto Rico, and 31 of the 50 states.[9,19] Rural or urban residence, altitude, topography, and proximity to water have not appeared to be determining factors in Japan.[18]

Male children tend to be affected more frequently both in Japan (male-to-female ratio 1.5:1)[18] and in the United States (1.8:1)[19] but the age of peak incidence is lower in Japan, where 85% of the children are younger than five years.[18,68]

Thus far, of the American cases, 57% have been in whites, 18% in blacks, and 25% in Orientals, predominantly of Japanese ancestry.[19] Although the cases are rare, secondary cases in twins and in siblings[43,69] and recurrences[21,70] have been reported.

Epidemiologically there has been little progress beyond the purely descriptive stage. An in-depth case-control study conducted by Yanagawa and Shigematsu[68] revealed that several factors were more prevalent among index cases than in their age- and sex-matched, hospitalized control subjects: previous history of cervical lymphadenitis, pharyngitis; vaccinations with Bacille Calmette-Guerin, vaccinia virus, poliovirus, diptheria-tetanus-pertussis; and maternal drug use during pregnancy (for allergy, respiratory infection, and vomiting). Differences in dietary habits, brands of milk, types of detergents, prenatal and neonatal problems, birthweight of

*References 20,22,24,25,29-32,36,56-67.

infant, and maternal age at the time of delivery between index cases and controls were not statistically significant.

LABORATORY FINDINGS

There is no single or battery of laboratory tests that is diagnostic for MCLS, but levels of acute-phase reactants, as measured by total WBC count, ESR, C-reactive protein, and serum α_2-globulin, are consistently elevated or increased. Leukocytosis (total WBC count > 15,000/cu mm) with leftward shift is commonly seen early in the illness and usually persists for one to three weeks. Leukemoid-type responses are observed rarely.[1,21,56]

The ESR is frequently elevated and the C-reactive protein is strongly positive at the time of initial presentation. In one series, the ESR appeared to have prognostic value: it tended to be higher and to remain elevated in patients in whom coronary artery stenosis or aneurysm developed.[71]

Other hematological abnormalities include mild normocytic, normochromic anemia and thrombocytosis. The latter finding becomes maximally apparent during the second and third weeks of illness.[21,25,30,57,72] Platelet aggregation is increased and may remain abnormal for months.[72] Thrombocytopenia has not been reported, and, if present, should suggest diagnoses other than MCLS.

Examination of clean-voided urine sediments typically reveals a few to many leukocytes during the acute phase of illness.[1,20,21,24-27] Urine obtained by suprapubic puncture, however, is reportedly free of WBCs.[21,58] Hematuria is observed infrequently,[21,39,43] whereas proteinuria occurs commonly.[1,21,39,42,59]

Mild CSF pleocytosis with lymphocytic predominance is occasionally seen.[1,20,21,25,31,39,60] Concentrations of CSF glucose and protein are normal.

Elevations in levels of serum bilirubin[30,36,56,59] and transaminases[24,27,30,36,60,61] may be observed. Serum electrolytes, urea nitrogen, and creatinine levels are normal.

There is no evidence for autoimmune phenomena: lupus erythematosus cell preparation† and rheumatoid factor‡ are negative; antinuclear antibodies§ and antibodies to DNA,[54] mitochondria,[54] striated muscle,[54] and myocardial sarcolemma[54] are absent. Quantitative immunoglobulin levels are generally normal for age, but elevations in class-specific immunoglobulins may be found.

Cultures of respiratory secretions, urine, feces, blood, CSF, pericardial fluid, lymph node aspirates, and postmortem tissues, as well as serological studies, for bacterial and nonbacterial agents are usually negative. Sporadic reports of the isolation of microorganisms from patients with MCLS have appeared, but their association with the disease process remains obscure (see "Etiology and Pathogenesis").

Transient abnormalities in ECG tracings, namely, prolongation of PR and QTc intervals, flattening of T waves, depression of ST segments, have been reported in 60% to 90% of Japanese cases.[73-77] Changes in ECG patterns may be as common in American cases.[78] Myocardial infarction patterns are encountered infrequently.

Coronary angiograms are reportedly abnormal in 30% to 60% of Japanese patients studied within two months after the onset of illness.[73-77,79] Abnormalities range from mild tortuosity and dilation of coronary arteries to aneurysm formation and marked stenosis. Spontaneous regression of coronary arterial lesions has been documented by serial angiograms.[73,74,77]

Cardiomegaly[74,76,79] and abnormal left ventricular function[75] (decreased ejection fraction, increased end-diastolic volume, elevated end-diastolic pressure, or mitral regurgitation) have been observed in patients with MCLS with abnormal coronary angiograms.

PATHOLOGY

Initially, MCLS was thought to be a relatively benign, self-limiting condition.[1] However, shortly after Kawasaki's original description, disease-related fatalities became apparent.[80,81] Most of the deaths occurred suddenly and quite unexpectedly during convalescence and were usually due to rupture of coronary aneurysms or to coronary thromboarteritis.[33,36,82]

The epidemiological features of 54 fatal cases of MCLS have been reviewed by Tanaka and co-workers.[33,34] Nearly 76% of the fatalities were in children younger than 2 years and only 5.4% were in children older than 6 years. While late deaths (over 180 days after the onset of illness) were registered, the majority of deaths (57%) occurred between the tenth and 29th days of illness. The male-to-female ratio of fatal cases was 3:1.

Heart and Coronary Vessels

The cardiovascular system is principally involved. Abnormalities apparent on gross and microscopical examination of necropsy materials are confined generally to the heart and the main coronary arteries. The heart is frequently enlarged and hypertrophied.[21,33,34,83] Numerous small, beadlike aneurysms are commonly found along the major coronary arteries, which are usually tortuous and dilated.[33,34,83] The coronary ostia may be partially or completely occluded by thrombi.[33,34,82,83]

The cardiac lesions of MCLS have been classified according to the duration of illness at the time of death.[83] If death occurs during the very acute phase of illness (stage I: zero to nine days), the pathological features, while profound, are limited to perivasculitis or microvessels (arterioles, venules, and capillaries) and of small arteries, including the vasa vasorum of the main coronary arteries. Aneurysms or stenoses are not evident. Acute pericarditis, interstitial myocarditis, and endocarditis may be observed.

Characteristic features of stage II (12 to 25 days) include panvasculitis and perivasculitis of the main coronary arteries, with stenosis or obstruction and aneurysm formation, pericarditis, interstitial myocarditis and endocarditis, and phlebitis of larger veins. Fibrinoid necrosis of the media occurs rarely.

Partial or total occlusion of the main coronary arteries due to granu-

lating thrombi or to marked intimal proliferation is typically observed in patients who die 28 to 31 days after the onset of illness (stage III). Angiitis or microvessels is absent, and myocarditis and endocarditis are less apparent.

Typically, severe scar formation and stenosis of the main coronary arteries are seen in stage IV (duration of illness at death, more than 40 days). Myocardial fibrosis and endocardial fibroelastosis are prominent. Inflammatory or ischemic changes of the atrioventricular conduction system (atrioventricular node, His bundle, left and right bundle branches) are observed commonly during all stages and are thought to be responsible for fatal arrhythmias.[83]

Deposits of albumin, fibrinogen, and IgG in the adventitia and tunica media of coronary arteries have been detected by immunofluorescence technique[84]; IgG has also been demonstrated within cardiac myofibrils.[84] It is unclear whether the localization of albumin, fibrinogen, and IgG is due to immune-complex deposition or to exudation of these proteins into areas of fibrinoid degeneration.

Other Vessels

Other small and medium-sized arteries (eg, renal, periadrenal, iliac, testicular, splenic) may exhibit intimal thickening, round cell infiltration, cicatrization, and, rarely, fibrinoid necrosis.[33,34,82]

Thymus

Autopsy records of fatal cases of MCLS indicate that the thymus is greatly reduced in size.[33,34] The medullary substance contains poorly formed Hassall's corpuscles. The number of lymphocytes in the cortex is greatly reduced and spindle cells are prominent. Whether thymic involution is the result of the acute illness or of corticosteroid administration in the more severe cases is unknown.

Lymph Nodes

Histological abnormalities in cervical lymph node biopsy specimens are nonspecific. Swelling of the endothelial cells and proliferation of immunoblast-like cells around postcapillary venules, and hyperplasia or reticulum cells have been described.[29,33,34,54]

Skin

Examination of skin biopsy specimens taken during the acute phase of illness has disclosed dilations of the intrapapillary capillary loops, endothelial fenestrations and necrosis, dermal edema, and perivascular cell infiltration consisting primarily of lymphocytes, marcophages, and mast cells.[85] These findings are nonspecific, but partly resemble those seen in delayed-type hypersensitivity reactions.

Pathology of Infantile Polyarteritis Nodosa (IPN)

The pathological findings of IPN have been well described.[15,86-88] Severe arteritic involvement and aneurysm formation of the main coronary arteries are typically found. Other musculoelastic arteries (eg, renal, periadrenal, splenic, pancreatic, pulmonary) are involved commonly. Arterial lesions are most often located at the bifurcations of vessels, and various stages of the arteritic process can be seen concomitantly. Fibrinoid necrosis in the media of medium-sized arteries tends to be inconspicuous or absent.[15,86-88] Endarteritis, a characteristic feature of the exudative phase that is marked by intimal proliferation, is prominent.

Myocardial inflammation in association with necrosis, and mild to moderate phlebitis, particularly of pulmonary veins, may also be observed.[15]

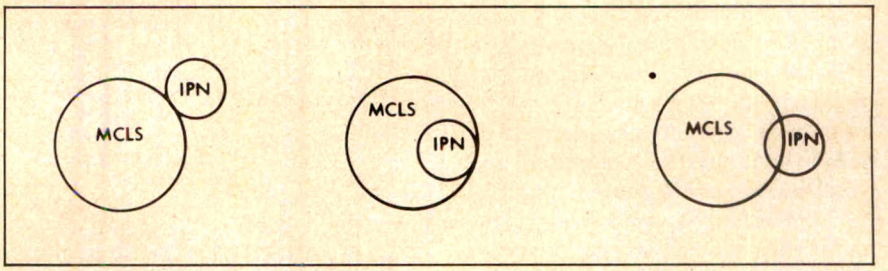
Relationship Between Fatal MCLS and IPN

The pathological similarities between fatal MCLS and IPN have been recognized by several investigators,[15,33,34,51,83] but the exact relationship of these conditions has not been firmly established. Specifically, the question of whether fatal MCLS actually represents IPN needs clarification. In part, the difficulty in resolving this issue rests on how the diagnosis of each condition is usually made. Infantile polyarteritis nodosa is rarely suspected or diagnosed prior to death[87,89]; it is a pathological diagnosis based almost entirely on morphological features. Conversely, MCLS is a clinical diagnosis based on a series of signs and symptoms.

There are several ways in which the relationship between fatal MCLS and IPN can be expressed schematically. The diagrams in Fig 2 may be used to represent the pathological relationship between these two conditions: the first postulate is that fatal MCLS and IPN are discrete entities that are mutually exclusive; the second is that fatal MCLS and IPN are one and the same entity; and the third is that fatal MCLS and IPN are distinctive but not totally separate entities and are not mutually exclusive.

Classifications based on morphological or histopathological changes, rather than pathogenetic mechanisms, have obvious limitations. Although the pathological features of fatal MCLS and IPN are indistinguishable, these terms may not indicate an identical disease process and the conditions may not have the same cause.

Fig 2.—Relationship between fatal mucocutaneous lymph node syndrome (MCLS) and infantile periarteritis nodosa (IPN). Fatal MCLS and IPN are separate and distinct entities that are mutually exclusive (left). Fatal MCLS and IPN are one and the same entity (center). Fatal MCLS and IPN are distinct but not separate entities that are not mutually exclusive (right).



Thus, from a pathological viewpoint, the data would merely suggest that fatal MCLS and IPN are closely related.

DIFFERENTIAL DIAGNOSIS

Clinical Picture

The clinical picture of MCLS is striking, but other infectious and noninfectious illnesses have similar features. Among these are staphylococcal scarlet fever, erythema multiforme minor, leptospirosis, and IPN. Others include erythema multiforme exudativum (Stevens-Johnson syndrome), streptococcal scarlet fever, toxic shock syndrome, rat-bite fever, tick typhus (Rocky Mountain spotted fever), rubella, rubeola, primary Epstein-Barr virus infection, enteroviral infections, roseola infantum, toxoplasmosis, juvenile rheumatoid arthritis, systemic lupus erythematosus, Reiter's syndrome, Behçet's disease, drug eruption with fever, and acrodynia.

Kawasaki realized that several diseases shared clinical features with MCLS, but he thought that the similarities were more apparent than real. He attempted to enumerate the distinctive findings of Stevens-Johnson syndrome, scarlet fever, acrodynia,[23,90] and MCLS. The differential clinical features of MCLS and other mucocutaneous disorders are shown in the Table.

Care must be exercised in the diagnostic evaluation of patients with acute febrile illnesses characterized by prominent mucocutaneous features. Fortunately, if close attention is given to detail, most of these conditions are easily distinguished from MCLS.

Reiter's syndrome[91] is rare in childhood and unreported in infancy. Prolonged fever, conjunctival hyperemia, evanescent erythematous rash, dysuria, and arthralgia or arthritis are typically present. Keratodermia blennorrhagia may be seen occasionally. Changes of the lips, the oropharyngeal cavity, and the peripheral extremities are conspicuously absent.

Travel to an endemic area, history of tick exposure, splenomegaly, and petechial rash are helpful distinguishing differences between tick typhus and MCLS. Although titer rises to *Proteus* OX-19 and OX-K may occur in both conditions,[63,64] complement fixation antibodies to *Rickettsia rickettsiae* are lacking in patients with MCLS.

Fever, conjunctivitis, and exanthem may be manifestations of several viral illnesses, including rubeola, rubella, Colorado tick fever, and enteroviral and adenoviral infections. Changes of the lips and peripheral extremities, however, are not known to occur in these illnesses.

Clinically, scarlet fever, caused by either group A *Streptococcus* or phage-group II *Staphylococcus aureus*, resembles MCLS, but there are important differences: the lips are not red, dry, or fissured; there is no erythema or indurative edema of the hands and feet; the febrile course is usually not prolonged. The diagnosis can be confirmed by recovery of the causative organism.

The toxic shock syndrome[92] primarily affects older children and adolescents. Typically, there is fever, a toxic appearance, generalized erythroderma, swelling of the hands and feet, conjunctival suffusion with possible progression to scleral hemorrhage, hypotension, hepatic and renal abnormalities, and in the more severe cases, disseminated intravascular coagulation. Focal infection with phage-group I *Sta aureus* is detected commonly with vaginitis prominent in females.

The clinical features of leptospirosis in childhood have been reviewed recently.[93] It is usually a mild, anicteric biphasic illness, but occasionally it may be an acute systemic disease with icteric hepatitis, renal involvement, shock, and evidence of extensive vasculitis. Fever, headache, myalgia, hyperemia of the ocular conjunctivae, and an erythematous maculopapular, petechial, or purpuric rash are fre-

Clinical Features of Mucocutaneo

	MCLS	Infantile Polyarteritis Nodosa	Erythema Multiforme Minor
Age, yr	Usually < 5	Usually < 1	All ages
Fever	Prolonged	Prolonged	Prolonged
Eyes	Hyperemia of the ocular conjunctivae	Hyperemia of the ocular conjunctivae	Hyperemia of the ocular conjunctivae; palpebral edema
Lips	Red, dry, fissured	Red	Erosions; ulcerations
Oral cavity	Diffuse erythema; "strawberry tongue"	Diffuse erythema	Erosions, aphthous-like ulcerations
Peripheral extremities	Erythema of palms and soles; indurative edema; periungal desquamation	Erythema of palms and soles; swelling of hands and feet; dry gangrene (rare)	No change
Exanthem	Erythematous, polymorphous	Erythematous, polymorphous	Erythematous, polymorphous; iris lesions
Cervical lymph nodes	Nonpurulent swelling; unilateral (frequent)	Nonpurulent swelling (frequent)	No change
Other	Meatitis; diarrhea; arthralgia and arthritis; meningitis; rhinorrhea (uncommon); ECG changes	Rhinorrhea and cough (common); diarrhea; ECG changes	Malaise; rhinorrhea; arthralgia; recurrent episodes

quent findings. Animal contact, especially dogs, cattle, swine, and rodents, is common. The diagnosis can be established by the isolation of leptospires from blood, CSF, or urine, by the detection of leptospires on dark field examination of urine, or by the demonstration of a fourfold or greater titer rise in leptospiral agglutinins.

The term erythema multiforme signifies a spectrum of disease ranging from a relatively mild illness referred to as erythema multiforme minor[94] to a severe, potentially life-threatening condition known as erythema multiforme exudativum or Stevens-Johnson syndrome.[95,96] At both ends of this spectrum, the collection of clinical features resembles that of MCLS. Differences are sufficiently discrete to differentiate MCLS from most cases of erythema multiforme exudativum,[95,96] which is characterized by extensive bullae formation, followed by erosion and a grayish-white pseudomembrane of the oral mucous membranes; ulcerations of other mucosal surfaces (eg, genital, anal, esophageal, tracheal); severe catarrhal conjunctivitis and chemosis with progression in some cases to uveitis, corneal ulcerations, iritis, or panophthalmitis; an erythematous polymorphous exanthem with vesicles, bullae, and extensive exfoliation.

The differences in clinical features between MCLS and erythema multiforme minor are less pronounced. Features common to both are prolonged fever, rash, conjunctival involvement, and changes of the lips and oral cavity. The conjunctival hyperemia and exanthem may be virtually indistinguishable. Whereas the characteristic cutaneous lesion of erythema multiforme minor is the iris or target lesion, this may be absent; instead there may be an erythematous polymorphous rash of symmetrical distribution involving the palms and soles and the extensor surfaces of extremities, particularly the dorsal aspects of the hands and feet. The mucosal lesions of erythema multiforme minor unlike those of MCLS consist of erosions and aphthous-like ulcerations of the lips and oral cavity. Indurative edema of the hands and feet, periungal desquamation, and cardiac or coronary artery involvement have not been described in erythema multiforme minor.

Usually MCLS can be differentiated from other mucocutaneous syndromes on clinical grounds alone. The possible exception to this is IPN, a disease of unknown origin and of nearly uniform fatality.[86-88,97,98] Retrospective tabulation of the clinical findings of IPN[86-88] indicates that a relatively constant clinical complex exists that is not unlike MCLS. The

h Node Syndrome (MLNS) and Other Mucocutaneous Syndromes

No change	Periungal membranous desquamation	No change	Swelling of the hands and feet; dry gangrene	Gangrene of the hands and feet (rare)	Swelling of the hands and feet	No change
Erythematous, polymorphous; iris lesions, vesicles, bullae, crusts	Finely papular erythroderma; Pastia's lines; circumoral pallor	Finely papular erythroderma; Pastia's lines	Erythroderma	Erythematous, maculopapular, petechial or purpuric	Maculopapular, petechial; centrifugal	Erythematous, evanescent
Nonpurulent swelling (occasional)	Nonpurulent or purulent swelling (frequent)	Nonpurulent or purulent swelling (occasional)	No change	Nonpurulent swelling (infrequent)	No change	No change
Malaise; cough, rhinorrhea, pneumonitis; vomiting; arthralgia; recurrent episodes	Malaise; vomiting		Headache; confusion; hypotension; icteric hepatitis; diarrhea; coagulopathy; renal injury	Headache; myalgia; abdominal pain; icteric hepatitis; meningitis	Headache; myalgia; photophobia; arthralgia; splenomegaly; stupor	Dysuria and urethritis; arthralgia and arthritis

principal clinical and laboratory features of IPN are persistent pyrexia, hyperemia of the ocular conjunctivae, generalized polymorphous exanthem, rhinorrhea, diarrhea, leukocytosis, and ECG changes. Other reported findings include reddened lips, diffuse erythema of the oropharyngeal mucosa, erythema of the palms and soles, swelling and rarely gangrene of the hands and feet, nonpurulent enlargement of the cervical lymph nodes, and hypertension. There are no apparent qualitative differences in the clinicopathological features of MCLS and IPN, but the majority of IPN cases do not fulfill at least five of the diagnostic criteria of MCLS.[15]

Relationship Between MCLS and Other Diseases With Mucocutaneous

A schematic representation of the clinicopathologic relationship between MCLS and other febrile illnesses with prominent mucocutaneous manifestations is shown in Fig 3. From the foregoing descriptions, MCLS and IPN do appear to be closely related. Whether MCLS represents the nonfatal form of IPN or whether IPN represents the fatal form of MCLS will probably be resolved only when the etiology and pathogenesis of these conditions are fully elucidated. In the meantime, the clinician should be aware of the clinical and pathological similarities and should diligently exclude potentially treatable, well-recognized causes of acute febrile mucocutaneous syndromes. This accomplished, and provided the diagnostic guidelines are fulfilled, the diagnosis of MCLS may be made.

ETIOLOGY AND PATHOGENESIS

The etiology and pathogenesis of MCLS are unknown. Some of the clinical and epidemiological features are compatible with infectious or postinfectious immunological processes or with reactions to •toxigenic substances. Presently, however, there are no prime candidates for this triggering event, and it has not been established that the interaction of several ubiquitous antigens comprises the precipitating stimulus.

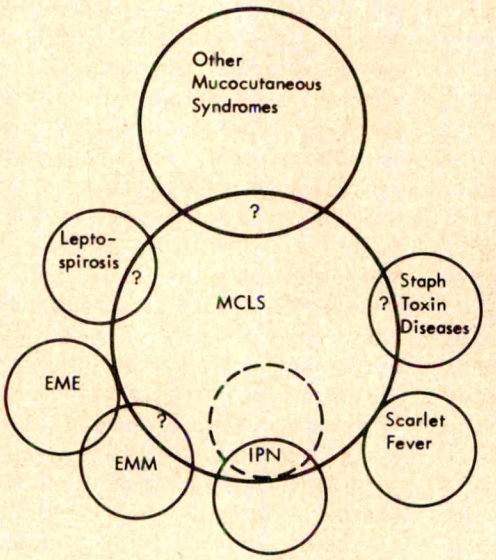

Fig 3.—Clinicopathologic relationship between mucocutaneous lymph node syndrome (MCLS) and other febrile illnesses with prominent mucocutaneous manifestations. EME indicates erythema multiforme exudativum; EMM, erythema multiforme minor; IPN, infantile polyarteritis nodosa; Staph, staphylococcal.

Infectious Agents

Microorganisms have been recovered from various specimens or detected in tissues of patients with MCLS. However, it is unclear whether these infections were concurrent with and independent from or antedated and were related causally with the development of MCLS.

Bacteria

Routine aerobic and anaerobic bacterial cultures of blood, urine, feces, CSF, pericardial fluid, lymph node aspirate, and respiratory secretions have been negative or have yielded normal flora. Serological testing for bacterial antigens, including *Salmonella O* and *H*,[21,29] *Brucella*,[21,36,56] paratyphoid A and B,[21,36] group A *Streptococcus* (streptolysin O, deoxyrinonuclease B), *Yersinia*,[29] and *Treponema pallidum*[29,63] have been uniformly negative.

Leptospires have been suggested as being etiologically involved in MCLS.[93] While leptospirosis may possibly mimic MCLS,[99] the total absence of leptospiral agglutinins in the sera of patients with MCLS belies any causative association.‖

Phage group 1 staphylococci capable of producing a new, dermal toxin have been recovered recently from the nasopharynx of an infant with typical MCLS.[92] *Staphylococcus aureus* has been reportedly isolated from other patients with MCLS. Coronary vasculitis has been observed recently in cases of toxic shock syndrome (unpublished data, September 1980 [J.K.T.]); however, the relationship of staphylococci to MCLS remains unsubstantiated.

Rickettsia

In 1973, Hamashima et al reported the detection of rickettsia-like bodies by electron microscopy in biopsy specimens of skin and cervical lymph nodes from eight patients with MCLS.[101] These rickettsia-like bodies were located within cytoplasmic vacuoles of macrophages and were also found clustered in the vascular lumen. They were Gram-negative and appeared as pink granules with Macchiavello stain. Isolation attempts were performed by inoculating guinea pigs and mice with whole blood from patients who were in the acute stages of MCLS.[102] Homogenates of liver and spleen prepared from these animals were then serially passaged and used to inoculate the yolk sacs of embryonated hens' eggs. An organism resembling rickettsia was recovered but was

‖References 21,30,36,45,56,60,63,64,100.

lost after storage at −80 °C for two weeks.[102]

Although rickettsia-like bodies have been reported by another group of investigators,[48] other efforts to duplicate Hamashima's results have been unsuccessful. Although Weil-Felix reactions may be positive in patients with MCLS,[63,64] they are usually negative.[21,36,37,42,61,62] Specific serological tests for known rickettsial diseases have also been negative.[20,29,36,40,61,63,65] The widespread geographical distribution, lack of definite seasonal pattern, absence of known vectors, and unresponsiveness to antibiotics make it difficult to reconcile a possible rickettsial origin for MCLS.

Viruses

Parainfluenza virus type 2,[56] adenovirus type 3,[70] herpes simplex virus,[70] and echo virus type 11,[70] have been recovered from patients with MCLS. However, conventional virus isolation attempts in tissue culture of respiratory secretions, feces, urine, CSF, pericardial fluid, conjunctival scrapings, joint fluid, and tissues taken at autopsy have generally failed to yield filterable agents.¶ Moreover, serological evidence of recent viral infection has been lacking in most studied cases. Significant rises in antibody titer have been absent to adenovirus,# herpes simplex virus,[23,29,43,45,63] cytomegalovirus,[21,29,31,45,49,62] varicella-zoster virus,[45,63] Epstein-Barr virus[56] (differential absorption test [Monospot][29,30,42,60-63,65] and heterophile[27,36,49,56]), vaccinia virus,[63] poliovirus,[23] coxsackievirus,[20,29] echo virus,[20,23,49] respiratory syncytial virus,[31,63] parainfluenza virus types 1, 2, 3,[29,49,63] Sendai virus,[43,45] mumps virus,[23,45] influenza A and B viruses,[21,29,31,36,45,61,63] rubeola virus,** rubella virus,[20,21,29,31,62,63,65] Colorado tick fever virus,[63,64] lymphocytic choriomeningitis virus,[29] reovirus types 1, 2, 3,[49] and hepatitis B virus.[36,53,56]

Serological testing and isolation techniques, however, have been far from exhaustive. Slowly replicating or noncultivable viruses could be involved. Additional unsuccessful attempts at virus isolation by inoculating a variety of cell lines and experimental animals, including guinea pigs, mice, and infant primates, and attempts at detecting filterable agents by immune electron microscopy have been reported recently by Melish et al,[78] but further attempts need to be made before a viral cause can be definitely excluded.

Others

There have been less-intensive searches for mycoplasmal organisms, protozoa, fungi, and chlamydial organisms. The few available isolation attempts and serological studies for these agents have been negative: cold agglutinins,[23,49,56,65] *M pneumoniae*,†† chlamydial psittacosis-lymphogranuloma-venereum,[21,29,36,45,63,64] *Toxoplasma gondii*.[20,29,36,43,56]

Toxigenic and Pharmacologically Active Substances

The relative absence of case clustering in MCLS is quite unlike patterns of illnesses caused by known environmental toxins. However, similarities in clinical findings between acrodynia and MCLS[90] have prompted examinations of biological specimens for heavy metals. Hair and serum mercury levels[21,54,90,103] have not been elevated in patients with MCLS. Serum lead levels have also been normal.[21]

Environmental pollutants or commonly used drugs and other chemicals may be pathogenetically involved, but none has been identified to date.[103]

Immunological Process

The significance of the nearly epidemic incidence of MCLS in Japan and of the disproportionate number of cases in children of Japanese ancestry in Hawaii is uncertain. Several human diseases are known to occur more frequently in genetically susceptible individuals as defined by specific histocompatibility antigens (HLA).[104,105] An association between HLA phenotypes and MCLS could not be shown by Matsuda et al[106] or by Melish et al.[78] Recently, however, in a much larger study comparing the HLA profiles of 205 unrelated Japanese children with MCLS with those of 500 normal, healthy unrelated control subjects, Kato et al[107] demonstrated that the frequency of HLA-Bw22 was significantly greater in the former group. Moreover, when HLA-Bw22J2, a subtype of Bw22 reportedly found only in Japanese, was examined, it was found even more commonly in patients with MCLS. The incidence of HLA-Bw22 is higher among Japanese than among Caucasians, and this antigen is virtually absent in some ethnic groups.[107]

While multiple factors are likely to be involved in the pathogenesis of MCLS, the usual manifestations of this disease seem more likely to develop in children genetically programmed for a specific immune response to certain as yet unidentified stimuli. Evidence for mechanisms involving immune-complex deposition or cellular- and/or humoral-mediated immunological injury in MCLS is scanty and in some instances contradictory.

Humoral Response

B-cell numbers,[54,108] proliferative responses to lipopolysaccharide,[108] and quantitative serum immunoglobulin levels[21,49,56,61,62] are generally normal for age. Elevation in levels of IgG,[63] IgA,[63] IgM,[24,29,63] and IgE[54,65,109] have been reported sporadically. Of these, IgE has received the most attention, primarily because increased levels have been found in two patients with IPN.[110] The role, if any, of IgE in the development of vasculitis in MCLS remains obscure, but it may act by promoting increased vascular permeability and subsequent antigen-antibody deposition and leukocyte migration.[44,109]

Tests for autoimmune phenomena, including antinuclear antibodies, lupus erythematosus cell preparations, rheumatoid factor, and antitissue antibodies, have been negative.

Total hemolytic complement (CH_{50}) are early components of complement (C3, C4, C5) have been examined by few investigators. The data are somewhat confusing because the temporal relationship of these determinations to the stage of illness is not usually

¶ References 21,24,28,30,32,52,53,62,63,65.

** References 20,21,29,31,43,45,62,63.

†† References 1,20,29,31,36,56,62,63.

stated. Levels of CH_{50},[30,54,56] C3,[43,54,62] C4,[43,54] and C5,[54] however, have been normal or elevated except in a few instances: in one well-studied case, Fossard and Thompson[44] reported depressed levels of CH_{50}, C3 and C4 during the acute phase (day 12) and elevated levels during recovery (day 40); transient depression of C3 during the seventh day of illness was reported by Melish et al[21] in one of four MCLS cases studied.

Circulating immune complexes have been detected rarely.[44,54,108] Whether actual deposition of such complexes occurs is unclear.

Cell-Mediated Response

T-cell numbers have been normal in the few cases studied to date.[54,108] Lymphocyte transformation with phytohemagglutinin has been normal,[108] but in mixed lymphocyte culture reactions, suppression of monocyte function has been reported during the acute phase of illness.[108]

Phagocytic Function

Peripheral neutrophils from patients with MCLS appear to have no defect in phagocytic capability or intracellular killing as determined by reduction of nitro blue tetrazolium.[54,111] Amplification of nitro blue tetrazolium reduction has been observed following the activation of neutrophils with *Proteus* OX-2 antigen.[111]

TREATMENT

Presently there is no accepted treatment for MCLS. Various treatment regimens have been tried on an empirical basis. The issues regarding therapy are several, but tend to be conditional because of insufficient knowledge about the etiology and pathogenesis of the disease process: (1) If an infectious agent is involved in the pathogenesis of MCLS, what role, if any, does antimicrobial chemotherapy have? (2) If the vasculitis of MCLS is the result of an overly exuberant immunological response by the host, what role, if any, do anti-inflammatory or immunosuppressive drugs have? (3) If the dreaded complication of MCLS, namely, coronary thrombosis, is due to thrombocytosis and accelerated platelet aggregation, what role, if any, do antiplatelet agents have? There is limited information on the efficacy of all treatment modalities, and additional controlled studies are needed.

Antimicrobial Agents

Nearly all infants and children with MCLS have received antibiotic therapy during the course of illness. Penicillins, cephalosporins, aminoglycosides, sulfonamides, macrolides, chloramphenicol, and tetracyclines have been prescribed. Although comparative trials have not been performed, none of these antibiotics have been associated with clinical improvement.

Antiinflammatory Drugs

Anecdotal accounts of the effectiveness of acetylsalicylic acid (aspirin)[39,54] and corticosteroids[27,44,66] in the symptomatic treatment of MCLS have appeared. However, in a controlled trial,[112] neither prednisolone (2 mg/kg/day) nor aspirin (100 mg/kg/day) seemed to affect the duration of fever or any other clinical parameter. Azathioprine was also ineffective.[112]

Recent data suggest that steroids may have a deleterious effect with regard to the development of coronary aneurysms.[113] Although the number of patients examined was too small, it appeared that the incidence of this adverse effect might be reduced if patients were also given low doses of aspirin (30 mg/kg/day).[113]

Antiplatelet Drugs

One of the stated goals of treatment of MCLS is the prevention of coronary thromboarteritis and of aneurysm formation. Prompt suppression of the accelerated platelet aggregation seen in MCLS has been achieved with aspirin and with flurbiprofen, D-L, 2-(fluoro-4-bi-phenylyl) propionic acid.[72,114] Doses of aspirin capable of reducing platelet aggregation have not altered the incidence of coronary aneurysms in patients with MCLS so treated, but may be effective in the prevention of sudden death due to coronary thrombosis.[113] Prolonged treatment with low doses of aspirin has been recommended by Kato et al[113] and T. Kawasaki, MD (verbal communication, 1979).

CONCLUSION

Although there appears to be considerable overlap between MCLS and other acute illnesses with prominent mucocutaneous manifestations, the six cardinal criteria do seem to define a distinct clinical entity. That is, there seems to be a definable group of infants and children whose clinical illnesses more closely resemble the original descriptions by Kawasaki than other previously well-described infectious or noninfectious diseases. However, this particular group may well be quite heterogeneous with regard to precipitating events.

As with other recently described diseases and syndromes, reasonable doubt and controversy continues to surround this elusive malady. The clinical and pathological features of MCLS and IPN are virtually indistinguishable, but their precise relationship remains to be defined. Like IPN[115] hypersensitivity has been speculated as being pathogenetically involved, but the dearth of immunopathological data does not permit definite conclusions.

Much remains to be learned about the etiology and pathogenetic mechanisms of MCLS. Until such time that a clearer understanding is available, the designation acute febrile mucocutaneous lymph node syndrome, which has been adopted by the World Health Organization, seems appropriate.

60 Years Ago in the AJDC

The Bacillus of Pfeiffer in Inflammations of the Respiratory Tract in Children

Studying the role of the bacillus of Pfeiffer in respiratory ailments, 1,000 sputum cultures were examined in the first three months of 1920. These cultures were taken by cough swabs from a variety of patients with pneumonia, other respiratory tract disease, measles, and a group of controls. Seventy per cent. of the entire group were under the age of 13 years, the rest were over 20 years of age. Results by categorical diagnosis were:

	% positive
101 Pneumonia patients	74
122 Other febrile respiratory disease	85
473 Simple colds	55
15 Tuberculosis	33
23 Measles	60
266 Controls	10

The authors comment that the prevalence of the bacillus of Pfeiffer was greater at that time than during an earlier period of 1909-10 when there was no influenza present in the population. They observed that its presence can frequently be traced to contact with someone sick with respiratory tract disease and conjectured that it may be "an early secondary invader whose presence modified the clinical and pathological picture."

Martha Wollstein, MD, Ralph C. Spence, MD, Babies' Hospital, New York (19:459, June 1920).

Special Feature

Radiological Case of the Month

Lionel W. Young, MD; Contributed by Mutsuhisa Fujioka, MD

Clinical History.—This 13-month-old baby boy was admitted to Children's Hospital of Pittsburgh because of wheezing of two days' duration. A chest roentgenogram was obtained (Fig 1). He had had meningitis at 3 months of age and recurrent otitis media and recurrent episodes of respiratory tract infection. He had been admitted to another hospital one month previously with a temperature of 42 °C and right upper-lobe pneumonia. The infant received antibiotics, his condition improved, and he was discharged home although he continued to have midanterior chest wall retractions.

On physical examination, his respirations were 40/min; pulse rate, 160 beats per minute; and temperature, 38.2 °C. He was in moderate respiratory distress, and midanterior chest wall retraction was noted. On auscultation, he had prolonged expiration with diffuse wheezing and bilateral rhonchi. Right bronchoscopy yielded purulent material and was followed by a right bronchogram (Fig 2).

From the Department of Radiology, Children's Hospital of Pittsburgh.

Reprint requests to Department of Radiology, Children's Hospital of Pittsburgh, 125 DeSoto St, Pittsburgh, PA 15213 (Dr Young).

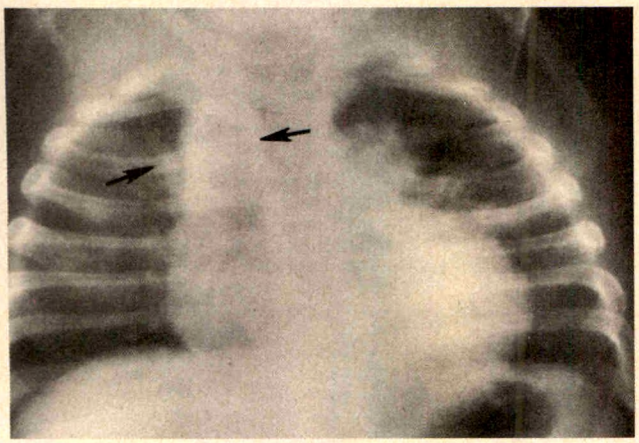

Figure 1.

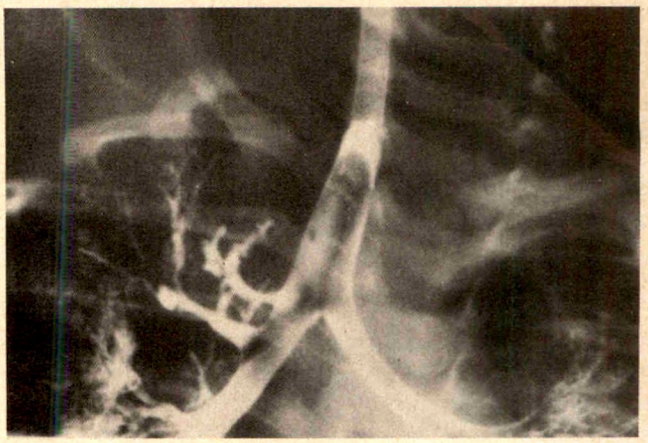

Figure 2.

Denouement and Discussion

Fig 1.—Posteroanterior roentgenogram shows area of increased density in medial portion of right upper lobe consistent with apical atelectasis and/or pneumonia.

Fig 2.—Bronchogram shows anomalous apical bronchus arising at tracheobronchial junction on right. Bronchi are irregular in shape and in distribution due to chronic inflammation.

Anomalous Apical Bronchus of the Right Upper Lobe

Anomalous bronchi of the right upper lobe are uncommon but relatively well recognized. Le Roux[1] found anomalous right upper bronchi in 30 (3%) of 1,000 bronchograms. Of special interest is their wide anatomical variation. Specifically, if a bronchus arises directly from the trachea, it is called a "tracheal bronchus." The tracheal bronchus may be a small rudimentary bronchus, a form of tracheal diverticulum,[2] or it may be the bronchus to the right upper lobe originating from the trachea.[3] A tracheal bronchus is the normal morphologic arrangement in pigs and other ruminants. Therefore, the segment of the upper lobe drained by a tracheal bronchus has been called "lobus porcinus" or "pig lobe."[4] On the other hand, an apical bronchus arising either from the right side of the trachea or from the lateral wall of the right primary bronchus before the lobar bronchi are given off is termed "pre-eparterial bronchus."[5] "Eparterial bronchus" refers to a bronchus over an artery and is the specific designation for the first branch of the normal right primary bronchus that courses over the right pulmonary artery. Variations from normal develop during periods when the segmental and subsegmental buds are being formed.[6]

In our patient, the apical bronchus of the right upper lobe arises at the junction of the trachea and the right main bronchus.

Anomalous bronchi may have no special clinical importance and they may be incidentally discovered during bronchoscopy, bronchography, or during surgery. The affected segment may be hyperinflated and take on a cystic form.[7] However, the lobe of an anomalous bronchus may also be the focus for atelectasis, and either atelectasis or cystic hyperinflation may predispose to recurrent pneumonia. Although recurrent pneumonia is often associated with pulmonary sequestration, this condition is extremely rare in upper lobes and does not have a normal bronchial tree despite having pulmonary blood supply.[8] The roentgenologic findings of a homogeneous density in the right upper lung area may be involvement of the lobe, but the finding is not specific. Loculated pleural effusion or a prominent right thymic lobe may simulate this.[9] Tomography may be helpful if anomalous bronchi are suspected and bronchoscopy and/or bronchography may be necessary to confirm the diagnosis.

Surgical resection of the affected segment is the treatment of choice in a patient with recurrent pneumonia to prevent additional episodes of pneumonia or other complications.[10] In our patient, the affected segment was resected and the patient has done well with no recurrence of upper respiratory tract infection.

Clinical Memoranda

Group A β-Hemolytic Streptococci Causing Pyogenic Gingival Cyst in Infancy

Localized gingival lesions in young febrile, irritable infants have recently been described, often in association with occult pneumococcal bacteremia. A review of the literature discloses eight such reported cases, many of which had concomitant ipsilateral buccal cellulitis.[1-3] This constellation of symptoms has been so typical that Yeager[3] suggested the presence of a cystic gingival lesion in a febrile infant with leukocytosis (1) should alert the clinician to the distinct possibility of concomitant pneumococcal bacteremia and (2) seems to be pathognomonic for this bacteremia. Recently, we cared for a febrile infant who had a cystic gingival lesion, mimicking a hemorrhagic preeruption dentigerous cyst, from which a pure growth of group A β-hemolytic streptococcus was obtained. The purpose of this report is to alert the pediatrician to the entity of a pyogenic gingival cyst of infancy and to stress the importance of aggressive diagnosis and antimicrobial therapy. We emphasize the multiple etiologies of these cysts, which have been reported only in infants younger than 1 year of age.

Report of a Case.—A previously well 6-month-old female infant was admitted to the hospital because of a two-day history of fever to 39.5 °C, coryza, irritability, and the recent onset of a well-localized gingival swelling. There had been no history of gross mouth trauma. The infant seemed acutely ill, with a temperature of 38.7 °C, a pulse rate of 130 beats per minute, and respiratory rate of 44/min. There was a violaceous, 1 × 1-cm, tender, fluctuant, thin cystic lesion on the left upper incisor area of the gingival ridge, associated with minimal swelling of contiguous upper lip. No underlying tooth eruption was seen or palpated. The rest of the results of the physical examination were unremarkable. The leukocyte count was 23,500/cu mm, with 57% neutrophils. The ESR was 42 mm/hr. Many Gram-positive cocci and polymorphonuclear leukocytes were seen on Gram's stain of fluid from incision and drainage of the cyst. Subsequently, group A β-hemolytic streptococci grew on culture of the drainage. No pathogen was recovered from pretreatment blood, throat, and nasopharyngeal cultures. Treatment with intramuscular penicillin G procaine caused defervescence in 24 hours, and a ten-day course of oral penicillin potassium was completed as an outpatient. On follow-up examination, the gingiva had healed completely.

Comment.—Localized pyogenic gingival lesions in febrile, irritable young infants have recently been described. To date, there have been nine cases reported in the literature.[1-4] Eight of these nine cases have been associated with pneumococcal bacteremia, and one case was due to localized infection with *Neisseria gonorrhoeae*.[4] The present case of localized gingival lesion owing to group A β-hemolytic streptococcus brings to ten the number of cases reported. All of the described patients were infants younger than 1 year of age who were febrile and irritable and often had a remarkable leukocytosis. All of the five children with gingival lesions reported by Burech et al,[1] the twins reported by Kehne et al[2] and the single case reported by Yeager[3] had concomitant ipsilateral buccal cellulitis and occult pneumococcal bacteremia. Bacteremia was not found in the infant with the gonococcal gum abscess nor in our patient.

Although the temporal relationship of these gingival lesions to pneumococcal bacteremia is apparent, the bacterial etiology of the mouth lesions in these patients remains in doubt. To date, only three of the eight reported lesions have been cultured prior to instituting antimicrobial therapy, and only one of these three yielded *Streptococcus pneumoniae* growths.[1] Unfortunately, serotyping of blood and gingival isolates was not carried out.

The relation of teething and trauma to the etiology of gingival lesions and bacteremia in this age group has yet to be proved although in older age groups, it is well known that dental manipulation can lead to bacteremia with α streptococci.[5,6] Although the group A β-hemolytic streptococcus is an infrequent cause of upper respiratory disease in infants,[7] it has been reported as a cause of a persistent watery rhinorrhea (nasopharyngitis), often with redness and crusting of the nares.[8] To our knowledge, this organism has not been previously reported as a cause of gross cystic gingival lesions in infants.

A simple hemorrhagic preeruptive dentigerous cyst should be differentiated from pyogenic gingival cysts. Both types of cysts occur in young infants. Fussiness may accompany an erupting tooth, and even fever (38.2 °C) has been reported with teething although this association is controversial.[9] The violaceous, hemorrhagic appearance of the cyst in our infant mimicked a dentigerous cyst, but the height of the fever, leukocytosis, and elevated ESR suggested a septic process. It is important for the pediatrician to appreciate the potential seriousness of cystic gingival lesions in febrile, fussy infants and to realize that any one of several pathogens (*S pneumoniae*, *N gonorrhoeae* group A streptococci) may be involved. We suggest the following steps in the approach to these cases: (1) Blood culture and leukocyte count with differential cell count should be obtained. (2) Cystic fluid for Gram's stain and culture should be obtained by aspiration or incision of the lesion. (3) The physician should evaluate the need for CSF examination and admission to the hospital. (4) The physician should start parenteral penicillin therapy pending the results of the just-mentioned studies.

Herpes Zoster in Early Infancy

Maternal chickenpox may result in one of the following two major clinical syndromes: early onset postnatal chickenpox or intrauterine infection.[1-2] Infection in the susceptible female early in gestation may rarely lead to severely affected infants who may display multiple congenital anomalies, as described in several similar case reports.[3-5]

Dermatomal localization, the sine qua non of shingles, has been a prominent feature of some of the case reports of the severely affected neonates as well as of a few cases of isolated disease early in life. This report documents the cases of two infants who had shingles during the first few months of life after intrauterine exposure to varicella-zoster virus.

Materials and Methods.—Standard virological procedures were used for the identification and isolation of varicella-zoster virus. Levels of complement-fixing antibody to varicella-zoster virus were determined by the methodology described by Brunell and Casey.[6] Immunofluorescence antibody was determined as previously reported.[7]

Report of Cases.—CASE 1.—A 16-year-old primigravida came during the third month of pregnancy to her obstetrician with crops of lesions at various stages of evolution, including vesicles, pustules, and scabs. A clinical diagnosis of chickenpox was made. Lesion aspirates were obtained for viral isolation in tissue culture, which subsequently yielded varicella-zoster virus. The course of maternal disease was mild and persisted for six days. The otherwise uneventful pregnancy ended with premature labor and delivery at 34 weeks' gestation.

The 2,420-g, preterm male infant was normocephalic and had no detectable defects; his Apgar scores were 9 and 10 at 1 and 5 minutes of age, respectively. At 9 weeks of age, the infant was hospitalized for pneumonitis when serial serum specimens were obtained for diagnostic evaluation.

At 4 months of age, he was seen for a rash of two days' duration. Grouped vesicles were noted in the L1-2 dermatome on the left. There had been no prior rash or known exposure to chickenpox. Varicella-zoster virus was recovered from vesicular fluid. Although the child's parents refused to return for a follow-up examination, a telephone call nine days later established that the rash had already resolved.

Seroconversion to varicella-zoster virus was noted in serial serum specimens obtained from the mother during and after the chickenpox infection. Antibody was present in cord blood serum as well as in the specimens obtained from the infant at the time of hospitalization for pneumonia and onset of illness, as given in the Table.

CASE 2.—An 18-year-old primigravida had uncomplicated chickenpox during the sixth month of gestation. Chickenpox was diagnosed by the patient's obstetrician based on clinical presentation. The index case proved to be a 7-year-old sibling who was diagnosed as having chickenpox by the child's pediatrician.

A completely normal, 3,130-g male infant was born at term. At 4 months of age, he was examined for a T3-4 vesicular eruption of two days' duration. Lesion aspirates yielded varicella-zoster virus in tissue culture. The child was otherwise asymptomatic. Growth and development were appropriate for age. All lesions were completely healed when examined two weeks later. There had been no previous rash or exposure to chickenpox. A four-fold antibody response by both complement fixing and immunofluorescence was determined.

Comment.—Contrary to earlier reports that suggested high risk for the conceptus, varicella-zoster virus infections in pregnancy are apparently benign because of inherent mechanisms that protect the fetus and newborn from, or at least ameliorate, disease in the case of in utero acquisition.[1] However, these protective barriers occasionally are breached and infection of the fetus or newborn can occur.

A few cases have been recorded in which varicella-zoster virus was believed to have been transmitted in utero during middle or late gestation and followed by the birth of a normal infant in whom shingles later developed, presumably due to reactivation of virus acquired during pregnancy.[8-10] The two babies described had shingles that were confirmed by viral isolation early in life after in utero maternal chickenpox. The course of disease was benign in both infants. This report further documents one aspect of the relationship between maternal varicella and the occurrence of shingles early in life.

Increased Amniotic Fluid α-Fetoprotein, Familial Hydrocephalus, and Renal Dysmorphology

The association of hydrocephalus and congenital renal disease as a syndrome complex is rare. Apert's, Meckel's, Robert's, and the orofaciodigital (type 1) syndromes have occasionally been reported with this combination. All of these have easily identified physical manifestations that allow syndrome identification as do trisomy 13, trisomy 18, and triploidy. In Zellweger syndrome, severe CNS defects are reported in association with renal and hepatic cysts where, apart from a distinctive facies, visible malformations may be minimal. The familial nephrotic syndromes and infantile polycystic disease of the kidneys have no characteristic external signs. This report is concerned with two brothers and a sister who had no external physical defect apart from hydrocephalus and in whom the kidneys were abnormal.

Family History.—The mother first came to our notice in 1975 when she was 36 years old. She and her husband are not related, and the family history was normal. In 1973, in the eighth month of her pregnancy, a stillborn male infant with hydrocephalus was delivered by forceps after craniotomy. No autopsy was performed. This pregnancy was complicated by deep vein thrombosis in the final trimester for which she was treated with warfarin sodium.

In 1975, in her second pregnancy, polyhydramnios developed at 32 or 33 weeks. An abdominal roentgenogram and amniography showed a hydrocephalic fetus. The amniotic fluid had an α-fetoprotein (AFP) content of 7.4 μg/mL (upper limit of normal, 2 μg/mL). Craniotomy was performed to permit vaginal delivery and an estimated 300 to 400 mL of CSF was drained. A male infant was delivered who, contrary to all expectations, survived. He weighed 3,300 g and had an estimated gestational age of 38 weeks. Apart from hydrocephalus (head circumference, 42 cm, with gross moulding) and bilateral simian creases, no other physical defects were found. The placenta weighed 850 g, slightly more than 25% of the infant's weight, but was otherwise unremarkable. Percutaneous ventriculography revealed obstructive hydrocephalus, with a block at the level of the third ventricle. A ventriculoperitoneal shunt was inserted at the age of 4 weeks.

In 1976, this mother again became pregnant; and during the 16th week, diagnostic amniocentesis was undertaken after ultrasonography. The ultrasonogram showed no abnormality, but the amniotic fluid AFP content was 780 μg/mL (upper limit of normal, 30 μg/mL). Chromosomal analysis of the cultured amniotic fluid cells showed a normal female karyotype (46XX). The pregnancy was terminated at 18 weeks by intra-amniotic instillation of prostaglandin F_{2}, and a female fetus was delivered. No gross defect was present on external examination. Skeletal roentgenographic survey was normal, but skull measurements on the roentgenograms were larger than expected from comparison with those of other fetuses of the same gestational age.

In view of the autopsy findings on this fetus, (described later), the male infant from the second pregnancy was admitted for investigation at the age of 16 months. He was asymptomatic and developmentally normal. Apart from arrested hydrocephalus (head circumference, 54.4 cm), bilateral indirect inguinal herniae, and simian creases, no external physical defects were present. Height and weight were on the 50th and the 97th percentile for his age, respectively. Severe but asymptomatic proteinuria was present, and the nephrotic syndrome was diagnosed.The BUN level was normal, the serum cholesterol level was elevated (801 mg/dL), and the serum albumin level was low (1.83 g/L). Titers for toxoplasma, Australia antigen and antibody, and cytomegalovirus were all within normal limits. Plasma and urinary amino acid patterns showed no abnormality. Intravenous pyelography and micturating cystourethrography showed no abnormalities. At the age of 18 months, a renal biopsy was performed when the herniae were repaired (see "Renal Biopsy").

Treatment with high-dosage prednisone was ineffective, and since then, the intermittent edema has been controlled by diuretic therapy. Severe eruptive xanthomata virtually resolved on dietary therapy.

At the age of 3 years, his head circumference was 55 cm. Computerized tomography of the skull and brain showed that the anterior horn diameters were 60 mm and that the posterior horns were slightly unequal, the left lateral ventricle being larger than the right but there was no shift. At the age of 4 years, he required shunt revision. The blocked drain was not infected, and the ventricular CSF was normal. The proteinuria and other features of the nephrotic syndrome have not changed since diagnosis, but he is now in a condition of mild chronic renal failure. There was no history in any of the pregnancies of overt maternal illness, infection, excessive drug intake, or threatened abortion.

Autopsy of Fetus.—The fetus was of normal size for gestational age, and pathological findings were confined to the brain and kidneys. Gross hydrocephalus was present, affecting both lateral ventricles and to a lesser extent the third ventricle, with the cerebral cortex reduced to a mere 0.4-cm width. In the lateral ventricles, small white nodules were visible on the ependymal surfaces. Microscopy showed that much of the ependymal lining of the ventricles had been replaced by a cellular reaction that was raised focally to form a granular ependymitis (Fig 1). The aqueduct of Sylvius was obliterated close to the third ventricle without marked gliosis, but the lumen of the aqueduct was replaced by glial cells and nests of ependymal cells forming rosettes and aqueductules separated by edematous brain tissue (Fig 2).

Both kidneys measured 1.4 cm in length, and on microscopy, they contained many cysts distributed through both cortex and medulla but mainly deep cortical area. Some cysts were glomerular while others resembled primitive ducts and ductules (Fig 3). An active and apparently healthy zone of glomerulogenesis was present. Formed glomeruli were also present and appeared normal on light microscopy. Electron microscopy was not possible as preservation of the tissues was too poor for accurate assessment.

Renal Biopsy: Microscopic Findings.—Sections from the renal biopsy specimen showed excessive numbers of immature glomeruli, which were small and had tufts consisting of a prominent outer layer of epithelial cells with a few mesangial cells in the center. Other glomeruli appeared nor-

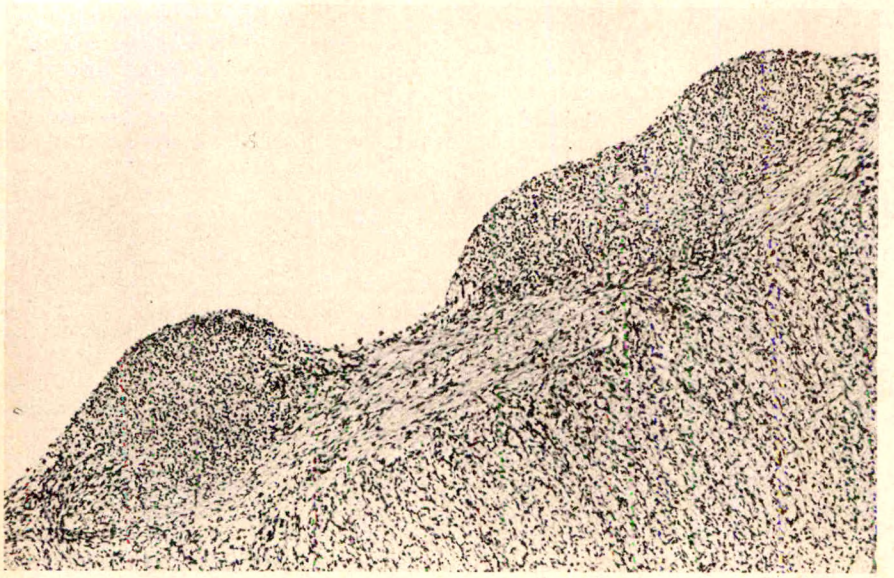

Fig 1.—Raised cellular nodules can be seen on ependymal surface of lateral ventricles (fetal autopsy findings). Level of destroyed ependyma is at base of nodules (hematoxylin-eosin, original magnification ×150).

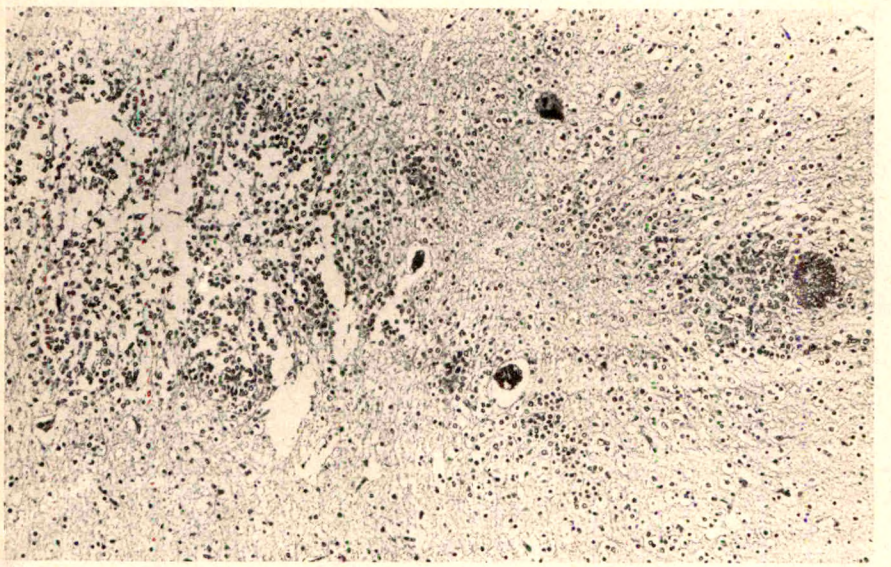

Fig 2.—Obliterated aqueduct of Sylvius showing replacement of glial cells and ependymal cells (fetal autopsy findings). Latter are forming rosettes. There is no observable increase in glial fibres (hematoxylin-eosin, original magnification ×150).

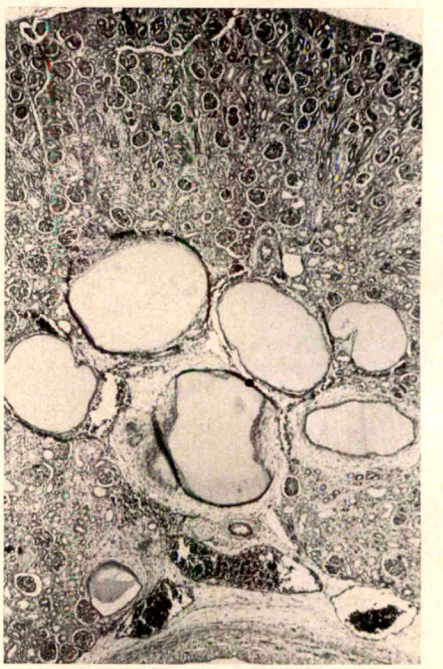

Fig 3.—Collection of cysts may be seen near corticomedullary junction of kidney. Renal pelvis is at bottom (hematoxylin-eosin, original magnification ×60).

mally developed, but there was a mild increase in mesangial cells and matrix with prominent capsular adhesions. Neither cysts nor dilated tubules were seen, and the glomerular basement membrane was normal. Electron microscopy showed foot process fusion and scattered, electron-dense deposits in the mesangium. Immunofluorescence studies demonstrated the presence of moderate quantities of mesangial and capillary loop C3 and IgM. The features were those of a mild, proliferative glomerulonephritis in a kidney containing many immature glomeruli.

Comment.—Interest in this set of siblings centers round the high amniotic fluid AFP levels for which no immediate cause was apparent. In neural tube defects, AFP reaches the amniotic fluid in excess either from a direct CSF leak or by passage across a defective membrane.[1] In instances where a small, skin-covered spinal lesion is present, the amniotic fluid AFP level is usually within normal limits.[2] A report[3] describing elevated amniotic AFP levels in association with isolated hydrocephalus has not been confirmed by others.[4] Known causes of elevated AFP level in the amniotic fluid, such as esophageal atresia, duodenal atresia, epidermolysis bullosa simplex, and exomphalos were excluded in our cases, leaving the possibility of congenital kidney disease with fetal proteinuria.

As the siblings had no gross external physical defect that would permit identification with one of the known syndromes in which hydrocephalus and renal lesions coexist, precise classification is not possible. The fact that the renal cysts in the fetus were not of the Potter type 3 category excludes diagnoses such as the syndrome of polycystic kidneys, internal hydrocephalus, and polydactyly.[5] Zellweger and the familial nephrotic syndromes should be carefully considered in the differential diagnosis. The cerebrohepatorenal syndrome of Zellweger comprises severe CNS defects (heterotopic cortex, periventricular cysts, and dysplastic changes in the olive and other areas), renal cortical (subcapsular) microcysts, and micronodular hepatic cirrhosis. Hydrocephalus has not been commonly found in this syndrome though one report mentioned mild dilation of the entire system[6] and

another[7] suggested that three infants with severe hydrocephalus and glomerular cysts may have suffered from the condition but the available data was too incomplete to allow confident diagnosis.

Affected infants have a characteristic facies with bossing of the forehead, and they have so far died by the age of 6 months.[8] In addition, the presence of hypotonia, failure to thrive, and cerebral dysfunction together with punctate calcification of cartilage are helpful in making the diagnosis during life. In the fetus from the third pregnancy, the liver was normal and the renal cysts closely resembled those found in previous cases of congenital nephrosis (Finnish type) seen at this institution.[9]

The results of the examination of the renal biopsy specimen of the surviving male infant, though not incompatible with the Finnish type of congenital nephrotic syndrome, showed no cysts, and the main features were those of a mild proliferative glomerulonephritis in a kidney still containing immature glomeruli at the age of 1½ years. He had a well-established nephrotic syndrome at the age of 16 months, and in view of the high amniotic fluid AFP level and the large placenta, it is likely that his kidney disease had an intrauterine onset. He shows no signs of liver pathology, and his present clinical course does not fit that described in the Zellweger syndrome or in congenital nephrosis (Finnish type).

Congenital nephrosis (Finnish type) is associated with high amniotic fluid and maternal serum AFP levels resulting from the glomerular leak of fetal serum protein,[9,10] which is thought to be due to faulty structure of the glomerular basement membrane. The condition is often, but not always, associated with microcysts of the tubules, particularly in the juxtamedullary area.[11] Congenital nephrosis (Finnish type) is usually fatal, and patients commonly die of infection in the first year or two of life though occasional infants survive longer. It always appears within 6 months of birth as the patients become symptomatic.

The course of this infant's unremitting nephrotic syndrome and the histopathological features are similar to those of the infantile-onset nephrotic syndrome that may be both familial and congenital.[12] It is suggested that this family has offspring who have both hydrocephalus and congenital renal disease associated with fetal and continuing postnatal massive proteinuria, ultimately becoming symptomatic as the nephrotic syndrome.

The familial nephrotic syndrome has been associated with congenital heart disease, deafness, urinary tract anomalies, and pyloric stenosis but is not associated with defects such as the gross hydrocephalus found in our three cases.[12] Although a spectrum of pathological changes occur in nonfamilial congenital hydrocephalus, aqueductal stenosis without substantial gliosis as seen in the fetus from the third pregnancy has been described in sex-linked congenital hydrocephalus,[13] and similar changes have been reported in experimental viral congenital hydrocephalus.[14,15]

In the female fetus, the fourth ventricle was not dilated but showed ependymal denudation similar to the grossly enlarged lateral and third ventricles so that a suspicion of inflammatory etiology is present. We have no histological information regarding the state of the male infant's ventricular systems to compare with the details available in the fetus. If intrauterine infection is the etiological factor in the fetal hydrocephalus, it must also be suspected of contributing to the hydrocephalus in the other two siblings. The maternal infection would therefore have to be present during a four-year period, with apparently no overt flare-up during pregnancy and no recognizable immunological reaction. However, there was definitely no history of maternal illness during the last pregnancy. In addition, most intrauterine infections leading to CNS abnormalities are also responsible for severe mental retardation with foci of cerebral necrosis and calcification. The male infant has no sign of these.

An autosomal recessive trait could explain all our cases and be responsible for a hitherto unrecognized syndrome of isolated hydrocephalus with associated familial nephrotic syndrome. The latter has a milder course than the Finnish type of congenital nephrosis and, like it, can be diagnosed antenatally. Elective termination of pregnancy may be indicated.

Confirmation of new syndromes can only be established when many cases are reported with similar features. We do not believe that any of our cases fits into predescribed categories and suggest that this may be a new syndrome. We cannot give precise etiology (genetic or environmental) but believe that others may have seen similar cases that would permit classification. As antenatal diagnosis is possible, there is further reason for the prompt elaboration of the syndrome.

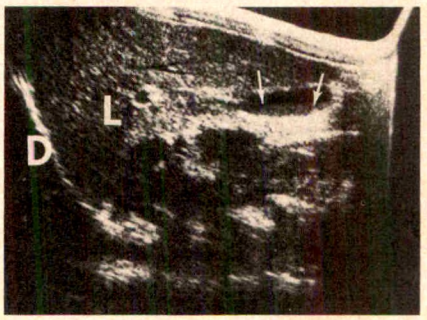
Cholelithiasis Associated With the Hemolytic-Uremic Syndrome

The hemolytic-uremic syndrome (HUS) exhibits a prodrome characterized by prominent gastrointestinal (GI) symptoms including vomiting, diarrhea that is often bloody, and colicky abdominal pain.[1-3] Persistent vomiting and abdominal pain continued after return of normal renal function and cessation of hemolysis in a 15-year-old girl with severe HUS. She was found to have cholecystitis because of calcium bilirubinate stones, which developed as a consequence of hemolysis. Cholelithiasis occurring as a complication of HUS has not previously been reported.

Report of a Case.—A previously healthy 15-year-old girl had anuria after five days of vomiting and bloody diarrhea. The diagnosis of HUS was made because of renal failure, anemia, thrombocytopenia, and the presence of many schistocytes on peripheral smear. The patient was then transferred to the Children's Hospital of Michigan, Detroit, where she remained anuric for 11 days. She required eight hemodialysis treatments and four transfusions of packed RBCs. Platelet counts first increased to more than 100,000/cu mm nine days after admission. Hemolysis slowly decreased, and by three weeks after admission, the serum haptoglobin level and peripheral blood smear were normal. Renal function improved, and her serum creatinine level stabilized at 0.7 mg/dL five weeks after admission. Results of hemoglobin electrophoresis and glucose-6-phosphate dehydrogenase assay, hemoglobin level, reticulocyte count, and peripheral smear findings were all normal several months after admission.

Despite improvement in hematologic and renal manifestations, severe anorexia and nausea continued. Nonbilious vomiting occurred whenever oral feeding was attempted. Physical examination showed moderate epigastric and right subcostal tenderness. Results of upper GI examination and liver function tests were normal. Serum amylase level was 350 to 400 units/dL (normal, 50 to 200 units/dL) (Amylotube method), and serum lipase value was 8.8 Cherry-Crandall units/dL (normal, 0 to 1.5 units/dL). Ultrasound examination demonstrated a normal pancreas, but it showed multiple opacities within a nondilated gallbladder (Figure). Normal-sized ducts were visualized on intravenous cholangiography. A two-week trial of conservative medical therapy was unsuccessful, and, consequently, a cholecystectomy was performed. No abnormalities of the pancreas were observed, and no adhesions and minimal inflammatory reaction were noted. Multiple small calcium bilirubinate stones and sludge were found in the gallbladder that was chronically inflamed and



Supine longitudinal ultrasonic scan of liver and gallbladder shows normal liver (L) and gallbladder that has multiple densities at its base (arrows). There was no shadowing behind gallbladder. On sonographic examinations in erect position, opacities did not move to most inferior surface of gallbladder. Nonshadowing nature of opacities and failure to move rapidly with gravity supports diagnosis of abnormal ultrasound with sludge (category 3).[11] D indicates diaphragm.

that had slightly thickened walls with minimal fibrosis. Intraoperative cholangiography with visualization of the pancreatic ducts showed no abnormalities. The surgical and pathologic findings are consistent with gallbladder disease of less than two months' duration. Recovery was uneventful. Despite absence of abdominal symptoms, the serum amylase level remained elevated (> 300 units/dL) until eight weeks postoperatively. During this period, an amylase clearance to creatinine clearance ratio was 1.27% (normal, 1% to 4%).[4,5] The serum creatinine clearance remained 0.7 mg/dL.

Comment.—Persistence of GI symptoms in a patient with HUS is unexpected after improvement of the renal and hematologic manifestations.[1-3] The elevated levels of serum amylase and lipase in this patient led to a tentative diagnosis of pancreatitis, and an abdominal ultrasound scan was obtained. The findings of nonshadowing opacities within the gallbladder and a normal-appearing pancreas explained the cause of the abdominal symptoms. The elevated serum amylase level can be attributed to decreased renal amylase clearance associated with the renal insufficiency of the HUS,[5,6] to the demonstrated biliary tract disease,[4] or to a combination of the two.

Since cholelithiasis is uncommon in this age group[7] and there was no history of unusual abdominal complaints nor evidence of a chronic hemolytic process, the gallstones seemed to have recently formed. The presence of gallstones in patients with chronic hemolytic processes, such as sickle cell disease and hereditary spherocytosis, is well known.[8,9] Neither is cholelithiasis mentioned as a complication of the HUS,[1-3] nor is an acute hemolytic process listed in several recent reviews of the etiology of gallstones.[7,10] The demonstration of gallbladder contents consisting of microcrystalline calcium bilirubinate calculus fragments supports the hypothesis that the acute hemolytic episode was the pathophysiologic event leading to cholelithiasis. Pigment gallstones should be suspected as a cause of abdominal pain in patients with acute, as well as chronic, hemolytic diseases, and they can be easily and safely looked for using ultrasonic scanning techniques.

Correspondence pertaining to material published in the JOURNAL will be published, if found suitable, as space permits. Submit double-spaced copy clearly marked "For publication" and signed by all authors; references should conform to JOURNAL format; maximum length: 500 words. Copyright assignment signed by all authors is required. The Editor reserves the right to edit such letters, which should be received within six weeks of publication of the JOURNAL article in question.

Infantile Cholestatic Liver Disease

Sir.—We read with interest the report by Rosenthal et al (JOURNAL 133:1195-1196, 1979) concerning infantile cholestatic liver disease associated with alpha$_1$-antitrypsin deficiency and the Pi-SZ phenotype. We have seen a similar patient who at 1 month of age had failure to thrive and conjugated hyperbilirubinemia. The only other clinical abnormality was a cholesterol level of 415 mg/dL. Rose bengal sodium I 131 did not enter the intestine.

An operative cholangiogram and open biopsy were performed before the results of the alpha$_1$-antitrypsin estimation were known. Bile ducts were present, but some observers thought they were small. Histologically, there was some increase in hepatic ducts and mononuclear infiltration. Diastase-resistant, PAS-positive granules were seen in both hepatocytes and Kupffer's cells. The alpha$_1$-antitrypsin level was estimated to be 90 mg/dL by radial immunodiffusion. The infant's Pi type was SZ, the father's SS, and the mother's MZ. By 2 months of age, the total bilirubin level was 3.3 mg, with the direct at 0.1 mg/dL, and the cholesterol was 292. At 5 months of age he was growing well and the cholesterol level had fallen to 164 mg/dL.

We had been concerned with the specificity of the histological examination of the liver biopsy specimen using PAS and diastase. Sections from a number of patients with jaundice, including galactosemia, unexplained fibrosis, hepatic ductular hypoplasia, and neonatal hyperbilirubinemia were prepared and stained in the same way. All of these patients had normal or elevated levels of alpha$_1$-antitrypsin. We could not detect any difference in the appearance of the PAS-positive granules between any of these samples and that from the infant with the SZ phenotype. We noticed that in published, later biopsy material, the granules are larger and there are clear halos around them. We wonder if other investigators have been similarly confused, particularly in light of the recent report of similar granules in a family with the Dubin-Johnson syndrome.[1]

The Danger of 50-mg Dapsone Doses to Children

Sir.—In reference to the article "Bullous Disease of Childhood" by Ramsdell et al (JOURNAL 133:791-794, 1979), please correct an error. Fifty milligrams of dapsone twice daily is *not* the correct dosage for the treatment of bullous disease of childhood (or any other disease of childhood). Childhood weight varies from about 2 to 80 kg. Because the common side effects of dapsone, namely, methemoglobinemia and hemolysis, are usually dose-related, the dosage of this drug should be calculated on a body-weight basis. The authors' use of 250 mg of dapsone per day in the treatment of their first patient, an 18- to 20-month-old child, seems excessive to me; later the dosage was lowered.

The dosage recommended to one of the authors by me as early as 1976[1] is 2 mg/kg. The dangers of a larger dosage were pointed out to me in conversation with R. Caputo, MD (Jan 11, 1979). He began treatment with a 4 mg/kg dose; within 24 hours, severe methemoglobinemia and hemolysis developed. The greater danger of casually presenting the 50-mg dapsone dose to the medical profession via this article became evident on Aug 24, 1979, just a few days after its publication, when Dr Virginia Weiss told more than 300 physicians at the International Congress of Pediatric Dermatology, Chicago, that the proper dosage for dapsone is 50 mg. Her source of information? The latest issue of the JOURNAL! I would appreciate knowing why the authors chose this dose.

GUINTER KAHN, MD

North Miami Beach, FL 33169

1. Kahn G, Rywlin AM: Acropustulosis in Infancy. *Arch Dermatol* 115:831-833, 1979.

In Reply.—We accept Dr Kahn's recommendation of 2 mg/kg/day as a reasonable and safe starting dosage of dapsone for the various dapsone-responsive dermatoses, including bullous disease of childhood and dermatitis herpetiformis. We agree that a milligram-per-kilogram dosage schedule for diseases that may occur at various ages (and body weights) is a more acceptable method of prescribing.

How Can You Help to Improve Your Community's Emergency Preparedness?

Consult these AMA Emergency Medical Care publications.

What happens when a medical emergency occurs in your community? Is your hospital prepared? Does your airport have adequate emergency facilities? How can *you* help to improve your community's emergency medical services?

These publications from the AMA's Department of Emergency Medical Services focus on setting up effective emergency care programs...in an entire hospital...in the hospital's emergency department... in an airport...within the community. You will find guidelines which will help you to develop workable solutions to your community's particular emergency medical problems.

TO ORDER: Write Order Department, American Medical Association, P.O. Box 821, Monroe, WI 53566. Please specify title, OP number, and include payment with your order. Allow 4-5 weeks for delivery.

PUBLICATIONS

Categorization of Hospital Emergency Capabilities (OP-387) $.55
The Commission on Emergency Medical Services of the AMA sets forth recommended guidelines for four categories of hospital emergency services for adults, children and infants, including newborns, that could function in community systems of emergency medical capabilities.

Emergency Department--Handbook for Medical Staff (OP-131 $2.00
How can the emergency department be an effective area for medical education? What are its legal implications? These and other related topics are explored in this manual which helps to establish workable solutions to problems in the emergency department.

Developing Emergency Medical Services--Guidelines for Community Councils (OP-386) $.75
In an effort to upgrade emergency medical care and reduce the number of needless accidental deaths, the AMA's Commission on Emergency Medical Services provides guidelines which deal with the establishment of community councils on emergency medical services and the various stages of developing good emergency medical services.

Airport Emergency Medical Services (OP-085) $.85
This new guide outlines the major functions of an emergency medical services plan, plus the key elements in providing such services, which should be common to all airports. Includes illustrations and appendices.

Books

Neonatal Surgery, ed 2, edited by P. P. Rickham, James Lister, and Irene M. Irving, 621 pp, $99.95, Boston, Butterworth Inc, 1978.

The 23 authors from Liverpool and Zurich have compiled a very interesting 50 chapters, organized to cover most of the conditions encountered by the pediatric surgeon who cares for the neonate. Each chapter has been well referenced by its author, and the numerous photographs from his or her personal experience add much to the clarity of the text. The first of eight parts is entitled "General" and covers a wide range of topics, from Dr Rickham's views on ethics to Nurse Hartley's suggestions on nursing care of the neonate. Part 2 covers trauma, tumors, and twins, each being covered concisely and expertly. The more unusual are covered in a brief but adequate way. Part 3, entitled "Head and Neck," succinctly covers the surgical approach to a few conditions that might require emergency surgery. Part 4 covers the rib cage, diaphragm, and lungs. The chapters on diaphragmatic hernia and esophageal atresia are especially well done. Part 5 covers the heart and great vessels. A large amount of information is presented, describing the lesion, its surgical therapy, and the postoperative care. In Part 6, the abdominal wall, alimentary, and biliary systems are presented, with the common and the unusual conditions being described. Here, especially, the influence of P. P. Rickham is apparent in the surgical technique. Part 7 encompasses the early management of congenital CNS lesions, such as myelomeningocele. Part 8 briefly covers the urogenital system, including intersexuality.

The book's editors have managed to use the book's 621 pages to their best advantage. Admittedly, some subjects are covered very briefly, but the reference list provides an adequate reading list for the reader in need of more information.

ROBERT W. EMMENS, MD
Department of Surgery
University of Rochester
Medical Center
Rochester, NY 14642

Neonatal Respiration, by L. B. Strang, 316 pp, $36.50, Philadelphia, JB Lippincott Co, 1977.

The science of neonatal respiration was spawned and nurtured to its current vigorous growth within the professional life spans of many current investigators, none of whom has contributed more to the study of developmental respiratory physiology than the author of this cogent book, L. B. Strang. The valuable longitudinal perspective afforded by a veteran and keen observer of a specialty science is often lost in the multiauthored or edited textbooks circulating today. That Dr Strang has decided to write a treatise on such a large and dynamic field as neonatal respiration is thus warmly welcomed by fellow students of the physiology of the newborn.

This is an excellent book. First of all, it is reassuring to note that it is possible, at some cost no doubt, to remain sufficiently abreast of all major subsets of one's specialty to write concise, orderly, lucid, well-illustrated, and well-referenced topical chapters that are suitable for both clinicians and researchers in the field. Second, the fact that the chapters are contained in a compact and relatively inexpensive book is a further recommendation.

The discussions of surfactant, pulmonary circulation at birth and of neonatal lung edema were my particular favorites; they have served well as outlines for clinical teaching. Apnea received less attention than is warranted by its clinical significance, and I am rather less impressed with the contribution of milk aspiration to clinical morbidity than is the author. The appended chapter on intravenous feeding seems out of place.

Principles of respiratory physiology intrude increasingly into the bedside formulation of clinical patient management in neonatal intensive care units. This book should prove to be a valuable clinical tool.

KARL SCHULZE, MD
Department of Pediatrics
College of Physicians and Surgeons
New York, NY 10032

Synopsis of Pediatrics, edited by James G. Hughes, 915 pp, $21.50, St Louis, CV Mosby Co, 1980.

Bigger and better, this fifth edition of a popular pediatrics book outgrows its designation of being a "synopsis" and emerges as a major, even though abbreviated, textbook that covers the essentials of the medical care of infants and children.

In a preface to the first edition, Dr Hughes indicated that his intention was to solve the riddle of combining brevity and clarity with a proper degree of comprehensiveness. In this edition, he has succeeded. The 32 chapters cover the field of pediatrics in a traditional fashion and in this edition two new chapters appear: "Adolescence" and "Child Abuse and Neglect." From the first edition through this one, the temptation to treat problems in a "cookbook" fashion has been resisted: mechanisms and reasons for disease, with a clear delineation of principles of treatment, have been used throughout. Nowhere is this better illustrated than in the outstanding chapter, "Common Fluid and Electrolyte Problems in Pediatrics," by James N. Ettledorf, MD, the master teacher who also took responsibility for this chapter in all other editions. In this chapter one will find, in only 13 pages, the principles that will allow the student or physician to manage and understand fluid and electrolyte problems in pediatrics. How the editor managed to get his 37 contributors to combine a practical thoroughness with brevity when writing their assignments is a secret that other editors should explore. All of the contributors have been or are associated with the University of Tennessee Center for

the Health Sciences, except Harry S. Shirkey, MD, who contributed the chapter on drugs in table form.

Careful editing, probably combined with much rewriting, has resulted in a clear style with unusual uniformity. Although the book contains 100 fewer pages than the previous edition, it is slightly larger in horizontal and vertical dimensions and has a new double column format that makes for easier reading. More tables, graphs, and photographs are used than previously. The book is bound in stain- and water-resistant material. It is unusually handsome, outside and in, and the publishers can present it with pride.

It is difficult to define the overall place of an abbreviated textbook of pediatrics. The author never intended that the book should replace the more conventional ones that have become distressingly more expensive as they grow larger and larger. This book will fill the needs of many physicians who want up-to-date knowledge on most pediatrics subjects. It is a handy and useful book to have around a hospital floor, a clinic, or in a physician's office. For those who feel that they cannot afford every new edition of traditional textbooks, it is also an economical way to have current knowledge at hand.

The Divorced Family (three-volume series), by Francine Spilke, 80, 82, and 32 pp, $6.95 each, New York, Crown Publishers Inc, 1979.

Current statistics are sobering: approximately 40% of marriages end in divorce. Five years after a divorce, 37% of children display severe psychiatric symptoms. The commonplace nature of divorce, its acceptance in everyday life, and its frequent treatment by television programs and popular movies have not diminished the need of parents and children for specific advice in coping with the stress associated with family disruption.

Francine Spilke, a discussion leader for groups of divorced parents and children, has written a set of three short books, the stated purpose of which is to "try to prevent children from becoming victims of their parents' divorce." The set is composed of a storybook for preschoolers, a book intended for older children and adolescents, and a parents' manual.

The storybook is entitled *The Family That Changed*, and violates Ms Spilke's own recommendation to avoid overloading the child with too much information at one sitting. There are acceptable ways to explain an impending divorce to one's young child, but to sit down with him and read aloud "Your mommy and daddy are not going to be married to each other anymore" seems unnatural and misguided. Other currently available storybooks (my favorite is Joan Lexau's *Emily and the Klunky Baby and the Next-Door Dog*, Dial Press, 1972) provide a better basis for explaining the implications of divorce.

What About Me? is written for children aged 9 to 15 years and more successfully deals with the feelings that separation engenders in both children and parents. It also deals sensitively with the issues of visits with the noncustodial parent and remarriage. Children are wisely advised to discuss with their parents the information offered in each chapter. The book suffers, however, from being written for different levels of development, and thus at times may appear either overly juvenile or too sophisticated. Many different family arrangements and problems are discussed that may not be pertinent to an individual child's situation.

What About the Children? is intended as a parents' handbook, but offers the same format and often the same information as the previous book. The author's intention is to provide insights into how children may behave under the stress of separation, and how some parents may conduct themselves to cause further problems for their children. Although parents are often very troubled at the time of divorce, this book assumes that the divorce occurs under ideal circumstances: amicable parents who respect themselves and each other, well-loved children, and solid parent-child relationships. Some valuable practical suggestions are given regarding the moving out of a parent, visiting days, and shared experiences between children and noncustodial parents. The effects of divorce on very young children are not dealt with, but the author successfully demonstrates the potentially harmful effects of disrupted parenting on older children.

These books are of uneven value. I do not recommend *The Family That Changed. What About the Children?* may be of limited value to professionals in terms of its practical insights. As a self-help guide, it will be read with interest by some insightful parents. *What About Me?*, however, is a more useful book and, while written for older children, it could probably be used to better advantage by parents as a guide to understanding children's feelings.

HAROLD A. KANTHOR, MD
Wilson Health Center
800 Carter St
Rochester, NY 14621

Book in Brief

Intoxications of the Nervous System, part 2, vol 37, *Handbook of Clinical Neurology*, edited by P. J. Vinken and G. W. Bruyn (578 pp, Amsterdam, North-Holland Publishing Co, 1979) (price not stated). A companion to volume 36 (see previous review), this multiauthored volume deals with a variety of intoxicants. Of particular interest to pediatricians are the chapters devoted to salicylisms and to hexachlorophene toxicity; one is reminded of the fact that this latter material is absorbed through the skin in amounts sufficient to cause CNS damage.

There is an interesting chapter on Jamaican vomiting sickness (which, incidentally, has some features in common with Reye's syndrome, such as hypoglycemia, fatty liver, and CNS edema) that is now known to be caused by the ingestion of uncooked unripe ackee, a fruit found in Central America, West Africa, and southern Florida as well as Jamaica. The intoxicant turns out to be an α-amino acid of unusual structure, called hypoglycin A, which interferes with gluconeogenesis, leucine metabolism, and acyl-CoA dehydrogenases. Additional chapters discuss other intoxicants: snake venoms, marine toxins, poisonous insects, antiepileptic and psychotherapeutic drugs, CNS stimulants, and organophosphates.

GILBERT B. FORBES, MD
University of Rochester Medical Center
601 Elmwood Ave
Rochester, NY 14642

This is not an easy time for her to stop smoking.

But it's not a good time for her baby to start.

The facts are in.

FACT: Women who smoke during pregnancy have smaller and lighter weight full term babies.

FACT: Their babies have more respiratory problems during the first critical years.

FACT: The incidence of stillborn infants and neonatal deaths is significantly greater.

FACT: The fetal oxygen supply is significantly reduced—the carbon monoxide in the blood significantly increased. There's more. Much more. Discuss the smoking hazard with your patients who are pregnant or planning a pregnancy. It may not be an easy time to quit smoking. But it's the right time.

While every precaution is taken to insure accuracy, we cannot guarantee against the possibility of an occasional change or omission in the preparation of this index.

Follow this blueprint for a more efficient, more profitable practice!

What is a well-designed, efficient medical office? What size facility do you need? How much will it cost? Should you build or rent?

You've probably asked yourself those questions. They're tough ones to answer and important ones. But you'll find the answers—detailed ones—the *Planning Guide for Physicians Medical Facilities,* published by the American Medical Association.

Whether you're building or remodeling your office or moving into your first practice setting, this guidebook offers invaluable practical information on planning your office for maximum efficiency. Contents include:

BASIC PLANNING: PLAN BEFORE BUILDING

Basic Planning • Unit Planning • Locating the Facility • Rent Versus Ownership • Professional Planning Assistance • Hospitals - Topography - Orientation • Choice of Property • Financing the Building and Equipment • Parking • Access and Parking

OFFICE CONSTRUCTION: INSIDE AND OUT

How Much Space • The Remodeled Building • Improving Leased Space • The New Building • Choice of Materials • Casework Walls - Partitions • Heating - Ventilating - Air Conditioning • Lighting and Electrical Service • Plumbing • Soundproofing • Landscaping

YOUR OFFICE INTERIOR: PUTTING THE PIECES TOGETHER

Reception Room • Reception and Business Office • Examining and Treatment Room • Consultation Room • Laboratory • X-ray Rooms • Utility Storage Areas • Furniture - Fixtures - Equipment • Color • Larger Facilities

OFFICE CONDOMINIUMS: WHAT YOU SHOULD KNOW

Improve the efficiency of your practice—Order this valuable guidebook today!

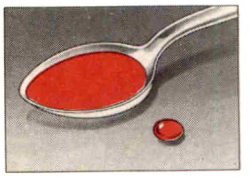
"All clear for landing."

Head's all clear, too!

Sudafed®



(pseudoephedrine HCl) 30 mg tablets/syrup

Opens the nose without closing the eyes

Don't let nasal/sinus congestion ground young pilots...relieve their symptoms with raspberry-flavored SUDAFED syrup or tablets.

Single-entity SUDAFED keeps young patients alert and on the go. It won't interrupt or interfere with their daily activities.

No alcohol. No aspirin. No antihistamines.

Just safe and effective decongestant action.

Be a hero to your young patients. Unclog their stuffed heads with SUDAFED.

Recommend Sudafed... For decongestion without drowsiness

ONE HUNDRED YEARS WELLCOME

Burroughs Wellcome Co.
Research Triangle Park
North Carolina 27709

Just a touch can transfer impetigo.

And just a touch of the right antibiotic can help clear it up.

Neosporin Ointment can help control minor cases of impetigo before other children catch it from your young patient, and it may be used as an adjunct to appropriate systemic therapy in more extensive disease. Neosporin Ointment provides broad, reliable antibiotic action against susceptible organisms—notably *Staphylococcus* and *Streptococcus*— with antibiotics that are seldom used systemically.

Neosporin® Ointment

(polymyxin B—bacitracin—neomycin)

Each gram contains: Aerosporin® brand Polymyxin B Sulfate 5,000 units; zinc bacitracin 400 units; neomycin sulfate 5 mg (equivalent to 3.5 mg neomycin base); special white petrolatum qs. In tubes of 1 oz and 1/2 oz and 1/32 oz (approx.) foil packets.

Warning: Because of the potential hazard of nephrotoxicity and ototoxicity due to neomycin, care should be exercised when using this product in treating extensive burns, trophic ulceration and other extensive conditions where absorption of neomycin is possible. In burns where more than 20 percent of the body surface is affected, especially if the patient has impaired renal function or is receiving other aminoglycoside antibiotics concurrently, not more than one application a day is recommended.

When using neomycin-containing products to control secondary infection in the chronic dermatoses, it should be borne in mind that the skin is more liable to become sensitized to many substances, including neomycin. The manifestation of sensitization to neomycin is usually a low grade reddening with swelling, dry scaling and itching; it may be manifest simply as failure to heal. During long-term use of neomycin-containing products, periodic examination for such signs is advisable and the patient should be told to discontinue the product if they are observed. These symptoms regress quickly on withdrawing the medication. Neomycin-containing applications should be avoided for that patient thereafter.

Precautions: As with other antibacterial preparations, prolonged use may result in overgrowth of nonsusceptible organisms, including fungi. Appropriate measures should be taken if this occurs.

Adverse Reactions: Neomycin is a not uncommon cutaneous sensitizer. Articles in the current literature indicate an increase in the prevalence of persons allergic to neomycin. Ototoxicity and nephrotoxicity have been reported (see Warning section).

Complete literature available on request from Professional Services Dept. PML.

PAIN GONE

while the antibiotic gets going

An effective adjuvant to systemic antibiotic treatment, AURALGAN promptly relieves the pain and reduces the inflammation of acute otitis media, while the antibiotic of choice fights the infection.

AURALGAN contains the topical analgesic action of benzocaine and antipyrine plus glycerin dehydrated...a decongestant so hygroscopic that it "blots up" excess moisture through the tympanic membrane, for relief of pressure and pain in the middle ear.

BRIEF SUMMARY
(For full prescribing information, see package circular.)
AURALGAN® Otic Solution
Each ml contains:

Antipyrine	54.0 mg
Benzocaine	14.0 mg
Glycerin dehydrated q.s. to	1.0 ml

(contains not more than 1.0% moisture) (also contains oxyquinoline sulfate)

INDICATIONS: *Acute otitis media of various etiologies*
—prompt relief of pain and reduction of inflammation in the congestive and serous stages
—adjuvant therapy during systemic antibiotic administration for resolution of the infection

CONTRAINDICATIONS: Hypersensitivity to any of the components or substances related to them./In the presence of spontaneous perforation or discharge.

DOSAGE AND ADMINISTRATION: *Acute otitis media:* Instill AURALGAN, permitting the solution to run along the wall of the canal until it is filled. Avoid touching the ear with dropper. Then moisten a cotton pledget with AURALGAN and insert into meatus. Repeat every one to two hours until pain and congestion are relieved.

HOW SUPPLIED: No.1000—AURALGAN® Otic Solution, in package containing 15 ml (½ fl oz) bottle with separate dropper-screw cap attachment.

...in acute otitis media

Auralgan®

OTIC SOLUTION

FULLY COMPATIBLE WITH SYSTEMIC ANTIBACTERIAL THERAPY. ON PRESCRIPTION ONLY.

Congenital Toxoplasmosis

Toxoplasmosis, an infection caused by the protozoan parasite *Toxoplasma gondii* occurs in many species of mammals and birds throughout the world. In man, toxoplasmosis is a very common infection with a prevalence ranging anywhere from 5% to 95% among young adults living in different parts of the world.[1] In the United States, by the end of the fifth decade of life, approximately 50% of the population is asymptomatically, yet chronically infected. Despite this high prevalence, the diagnosis of toxoplasmosis is only rarely entertained as the cause of illness. However, the clinical importance of this infection derives from the fact that it may mimic a variety of clinical syndromes, it may cause severe, even fatal infection in the immunologically compromised host, or as we are reminded by Dr Stray-Pedersen in this issue of the JOURNAL (p 638) that, *T gondii* may be transmitted from mother to fetus.[1-4]

OCCURRENCE OF CONGENITAL TOXOPLASMOSIS

Because congenital toxoplasmosis occurs only when maternal infection is first acquired during pregnancy, defining the risk of acquisition is of paramount importance if one is to assess the magnitude of this problem.[3] After prospectively studying more than 8,000 pregnant women, the Oslo study demonstrated that the rate of acquisition of toxoplasmosis during pregnancy was 1.1 to 1.3 per 1,000 pregnant women. By contrast, in the United States the rate of seroconversion in the general population between the ages of 15 and 35 years, is 1.25% to 1.2% per year.[1] Thus, we can anticipate that approximately six of every 1,000 pregnant women will acquire toxoplasmosis during the nine months of gestation. A recent study from the Oregon Public Health Laboratory has confirmed these figures after testing nearly 100,000 pregnant women over a six-year period. In this study, seroconversions occurred at a rate of 0.63% per year or in one of every 200 pregnancies.[5] Despite these high figures, the rate of congenital toxoplasmosis in the United States ranges between two and one per 1,000 live births. Two prospective studies performed in this country, one in Birmingham, Ala and the other in New York City showed an incidence of one per 750 and one per 1,350 live births, respectively. If these figures are extrapolated to the population at large, then an estimated 3,300 infants are born each year with congenital toxoplasmosis.[1]

In this issue of the JOURNAL, Dr Stray-Pedersen reports that three of 11 mothers who acquired toxoplasmosis during pregnancy transmitted the infection to their unborn babies. Previous studies, namely those of Remington and Desmonts[1] and Desmonts and Couvreur,[3] had established that nearly 45% of women who acquire toxoplasmosis during pregnancy give birth to congenitally infected infants. The rate of transmission is directly related to the gestational age at the time of infection. For instance, in the French study the incidence of fetal infection went from 17% to 25% to 65% when maternal toxoplasmosis was acquired during the first, second, and third trimester of gestation. However, as one might expect, fetal damage was inversely related to gestational age. This phenomenon explains why the majority of infants born with congenital toxoplasmosis appear normal or only moderately sick at birth. Previous studies have established that 70% of the infants born with this infection are asymptomatic, 10% are born with ocular involvement only, and the remaining 20% suffer from a symptomatic infection that manifests itself as either an acute generalized form of illness or as neurologic sequelae.[1,4] In Dr Stray-Pedersen's study, only one of the three infants with congenital toxoplasmosis was recognized as having hepatomegaly at birth.

Despite early diagnosis and treatment, the more severe form of congenital toxoplasmosis leads inevitably to debilitating sequelae like impaired vision and psychomotor retardation. However, of greater medical importance is the fact that the subclinical form of this disease may also lead to serious untoward sequelae.[2,4] In our personal experience, chorioretinitis, which in some cases results in blindness, or varying degrees of mental retardation have developed in most patients who were asymptomatic at birth. These findings, gathered after years of tedious longitudinal studies, indicate that despite its low incidence congenital toxoplasmosis is a significant health hazard.

NEED FOR ACCURATE DIAGNOSIS

The first step in preventing the deleterious effects of congenital toxoplasmosis is accurate diagnosis. The study published in this issue together with a fairly impressive body of information published by several investigators in both Europe and the United States, demonstrate the need for a widely applicable serologic method to test for acute toxoplasmosis during pregnancy. Since congenital toxoplasmosis occurs only when the infection is first acquired during gestation, the documentation of antibodies before conception indicates there is no risk of fetal infection in a future pregnancy. Conversely, a seronegative woman must be considered susceptible; in the United States nearly 80% of pregnant women will fall into this category (this is the rate of susceptibility at approximately 20 to 25 years of age).[1] Since in the vast majority of cases acute *Toxoplasma* infections are asymptomatic, serial determinations of antibody would be required to identify primary infections during gestation. These measurements can be done by several different assays, but clearly the most widely accepted are indirect immunofluorescence and Sabin-Feld-

man dye tests. A serious dilemma is posed by those pregnant women who have a high antibody titer on their first prenatal visit; (titers of ≥ 1,024 suggest recent infections). The most important diagnostic aid in these cases is the determination of specific IgM antibodies.[1] Dr Stray-Pedersen provides additional support to this approach since ten of the 11 women considered at high risk by the more classic serologic assays were also positive in the fluorescent antibody (FA)-IgM tests. In contrast, none of the 23 patients considered at minimal risk possessed IgM antibodies. In the past, as in Dr Stray-Pedersen's study, attempts at prenatal diagnosis of fetal infection by means of determinations of IgM antibodies in amniotic fluid have been unsuccessful. However, her report of isolation of *T gondii* from the amniotic fluid in two of the three confirmed cases of congenital toxoplasmosis must be viewed as a contribution of major significance. *Toxoplasma* organisms can be isolated by inoculation into mice or monolayers of tissue cultures. The latter method is of particular value because it is becoming more and more available due to the rapid expansion of diagnostic virology laboratories. Clearly, larger studies should be undertaken in the future to better define the value of this diagnostic approach.

It is obvious that the recognition of acute toxoplasmosis during pregnancy and more specifically the recognition that fetal infection has occurred could lead to therapeutic intervention. For this purpose European investigators have used spiramycin, an antibiotic that is not available in the United States. Their results have not been very successful due primarily to poor transplacental transfer. An alternative is the use of pyrimethamine (Daraprim) and sulfadiazine, a combination of proven efficacy. However, because it is potentially teratogenic the use of this drug combination must be carefully pondered, particularly in the first trimester of pregnancy. If treatment is to be given during this period, most investigators recommend the use of sulfonamide drugs alone. Finally, and only after an irrefutable diagnosis of toxoplasmosis acquired during the first trimester is made, one could consider therapeutic abortion.

The diagnosis of congenital toxoplasmosis after birth is normally made by demonstrating persisting or rising levels of specific IgG antibodies, by the presence of IgM antibodies in cord or neonatal sera, or by isolating *Toxoplasma* organisms from placenta or cord blood.[1,4] Of these methods, serial determination of IgG antibodies is the only one that is readily available to most clinicians. Its main drawback is the four to six months required to confirm the diagnosis, a delay that is undesirable in view of the progressive nature of this disease. The use of the FA-IgM test has had supporters and detractors, but for all practical purposes the results of this test in diagnostic laboratories are generally unreliable due to a variety of technical problems. This contention is further supported by Dr Stray-Pedersen's observations that none of the three infants with congenital toxoplasmosis had specific IgM antibodies on their cord sera nor did a measurable IgM response develop afterwards. In contrast, in two of these cases *Toxoplasma* organisms were isolated from placenta. Hopefully this particular method will be further investigated in the future.

Diagnostic evaluations are normally entertained only for those patients in whom the diagnosis of congenital toxoplasmosis is suspected on clinical grounds. This means that approximately 80% of all infants born with this infection would never be identified until perhaps years later when untoward sequelae become apparent. This is the rationale behind the programs for screening asymptomatic neonates. Those that have been proposed include the simple quantification of IgM in cord sera or the detection of *Toxoplasma* IgM antibodies in the same specimen.[4] Due to their low sensitivity and poor specificity neither has achieved broad acceptance.

Because of these diagnostic difficulties, in the past two years Dr Stray-Pedersen as well as two groups of investigators in the United States and France have tried to ascertain the diagnostic value of an assay that measures the blastogenic response of lymphocytes incubated with *Toxoplasma* antigens.[6,7] The rationale behind this approach is that lymphocyte transformation reflects a specific immune response in the newborn and does not appear to be influenced by maternal immunity. This technique could prove particularly valuable during the first six months of life, a period in which maternally derived IgG antibodies interfere with serologic diagnosis. The number of patients studied by these groups of investigators is simply too small to reach a definitive conclusion. The results, to date, are somewhat disappointing. Dr Stray-Pedersen tested two of the three congenitally infected infants during their first year of life and found that both were negative. At 12 months of age the lymphocytes from all three patients responded but only minimally. Wilson et al[7] reported that 21 of 25 patients with congenital toxoplasmosis had a positive lymphocyte transformation response. It is noteworthy, however, that two of the negative responses occurred among the three infants tested between 1 and 3 months of age. In our study that included 13 patients, all gave a positive result but none was less than 1 year of age at the time of evaluation. Thus, it seems that assessing cell-mediated immunity, at least with a lymphocyte transformation assay, during the first 4 months of age is not much better than the serial detection of IgG antibodies by indirect immunofluorescence or Sabin-Feldman dye tests.

These difficulties in establishing the diagnosis of congenital *Toxoplasma* infection in asymptomatic infants have seriously limited the performance of studies to determine the efficacy of treatment. Although the incidence of congenital toxoplasmosis is low and the damage limited, I am convinced that these issues will need to be addressed in the future. If massive screenings can be standardized and performed at a reasonable cost, the best strategy would be to screen for primary toxoplasmosis during pregnancy. This would give us the opportunity for therapeutic intervention immediately or soon after the fetus is infected. If this is not feasible

or turns out to be too expensive, then neonates may have to be tested by serologic or other means. None of the methods now available to the clinician are specific and sensitive enough to meet the criteria for a massive screening program of newborn infants.

60 YEARS AGO IN THE AJDC

Active Immunization Against Diphtheria in a Large Child-Caring Institution

In the Home for Hebrew Infants in New York City diphtheria had been an endemic disease for a number of years. The year 1915 saw the death of six children from the disease, in addition to many more clinical cases that occurred. The Schick test, first used in 1908 and published in 1913, was used by Dr Blum to determine the susceptibility of children to diphtheria. (An inflammatory reaction at the site of injection of diphtheria toxin into the skin indicates tissue antibody is insufficient to neutralize the injected toxin.) Of 1,076 children tested, 37.7 per cent. had positive Schick tests. Among infants 1 to 6 months, 21.6 per cent. had positive Schick tests. In infants 6 months to 1 year, 62.6 per cent. had positive Schick tests. In those children 4 to 6 years of age, 20.9 per cent. had positive Schick tests. None studied were over 6 years of age.

Immunization was carried out with a toxin-antitoxin mixture and was done on a total of 252 children who had positive Schick tests. These children were then retested by Schick tests at monthly intervals thereafter and the following results were observed:

	Time Interval after Injection	Number Tested	Results		Per Cent. Negative
			Positive	Negative	
Group 1.	3 to 4 months	252	68	184	73
Group 2.	9 to 10 months	130	12	118	91
Group 3.	22 months	50	0	50	100

(The decreasing numbers represent children leaving the institution over the course of the study).

Most significantly, there were no observed diphtheria cases among any of the immunized subjects over the subsequent five years.—Julius Blum, MD, New York (20:22-28, July 1920).

Infants Potentially at Risk for Congenital Toxoplasmosis

A Prospective Study

Babill Stray-Pedersen, MD

• **Fifty-two children were selected as being potentially at risk for congenital toxoplasmosis by serologic testing of 8,043 pregnant women in the Oslo area. These infants were then studied during the neonatal period and subsequently followed up for three years. Three were found to be congenitally infected with *Toxoplasma gondii*, and one infant was dysmature at birth. The diagnosis was confirmed by persistent dye-test antibodies and by recovery of parasites in placenta and/or amniotic fluid. The *Toxoplasma* indirect fluorescent IgM-antibody test remained negative, while measurements of cord IgM and IgA levels and serial estimations of specific antibody load supported an early diagnosis. The specific cell-mediated immunity, as measured by the in vitro lymphocyte stimulation test, turned positive at 1 year of age and then increased markedly during the second and third years. The lymphocyte responses of the uninfected children, however, remained negative. The infected children received pyrimethamine/sulfadiazine treatment during their first year, with no clinical signs of congenital toxoplasmosis.**

(*Am J Dis Child* 134:638-642, 1980)

From the Department of Obstetrics and Gynecology, Rikshospitalet, University of Oslo; the National Institute of Public Health; and the Norwegian Defense Microbiological Laboratory, Oslo.

Reprint requests to Department of Obstetrics and Gynecology, Rikshospitalet, Oslo 1, Norway (Dr Stray-Pedersen).

It has been recognized for years that the parasite *Toxoplasma gondii* may cause congenital infection[1] with the classical tetrade of clinical manifestations including chorioretinitis, hydrocephalus, convulsions, and intracerebral calcifications.[2] Recent investigations have shown that in many congenitally infected children, these characteristic symptoms may be partially lacking or absent at birth.[3,4]

The neonates with clinically apparent disease have a poor prognosis; mortality is high and they often show mental retardation and multiple organ involvement.[5] The neonates with inapparent congenital infections, however, may remain asymptomatic for months or years, but subsequently the disease may manifest itself in symptoms involving the brain or the eye.[6-8] Damage caused by the parasites, especially in children with silent infections, may perhaps be prevented if specific treatment is given immediately after birth.[3,4,9] Consequently, the diagnosis should be established as early as possible in the neonatal period.

For editorial comment see p 635.

The incidence of congenital *Toxoplasma* infections in Norway might be expected to be 1 to 2/1,000, according to prevalence studies of acquired infections.[10,11] To study the actual risk of congenital toxoplasmosis in our country, 8,043 pregnant women were screened for *Toxoplasma* antibodies.[1] This article presents the results obtained in a three-year follow-up study of 52 children delivered in pregnancies potentially at risk for congenital transmission.

SUBJECTS AND METHODS

Subjects

The study included 52 infants identified in a prospective screening based on serologic examination (dye test and indirect fluorescent IgM-antibody test [IgM-IFAT]) of 8,043 paired blood samples from pregnant women in the Oslo area during the years 1974 and 1975.[12] The infants were divided into three risk groups according to the approximate time of the maternal infection.

Group 1 (high risk) consisted of 11 children (patients 1 through 8 and 11 through 13) whose mothers acquired the infection during pregnancy. The dye test in eight of these mothers (of patients 1 through 8) had converted from negative to positive; one mother (of patient 11) had shown a substantial rise in dye-test titer; and two mothers (of patients 12 and 13) had high titers (≥ 300 IU/mL). Ten of the 11 women had a positive IgM-IFAT during pregnancy.

Group 2 (minor risk) included 18 infants whose mothers acquired the infection shortly before conception. In seven mothers, the dye-test titer was high, but the IgM-IFAT was negative in the first trimester; in the remaining 11 mothers, the dye-test titer was moderately high (100 to

300 IU/mL) and the IgM-IFAT was positive in the first half of pregnancy.

Group 3 (minimal risk) comprised 23 children whose mothers' infections were acquired months before conception. The dye-test titer of these mothers was moderately high, and the IgM-IFAT was negative throughout the gestational period.

Study Protocol

Amniotic fluid, placenta and umbilical cord tissue, and cord blood were obtained at delivery, and the infants were observed in the nursery for at least eight days during which serologic, clinical, ophthalmoscopic, and radiologic examinations were performed. The infants in group 1 were similarly examined at 6, 12, and 24 months of age, and motor and mental development was assessed at 36 months of age. Blood samples were drawn monthly from all of the children during the first six months of life, then every third month until 18 months of age. Thereafter, serum samples were collected annually from group 1 infants. These infants are still being followed up.

Treatment

All neonates in group 1 received daily doses of spiramycin (Rovamycin [Great Britain]; no comparable US product), 50 mg/kg/24 hr, for three weeks. When evidence of congenital infection was obtained, a three-week course of pyrimethamine (Daraprim), 1 mg/kg/24 hr, sulfadiazine, 50 mg/kg/24 hr, and folic acid, 0.1 mg/kg/24 hr, was given; this regimen was repeated twice during the first year of life (Figure). The infant received one daily oral dose of a powder mixture of the drugs. This was administered at home under the supervision of a pediatric clinic. During the pyrimethamine treatment, weekly blood cell and platelet counts were performed.

Laboratory Tests

The blood samples were always examined together with specimens previously collected from the infant and the mother and stored at −20 °C.

For the dye test (DT), a micromodification of the classic Sabin-Feldman method was used,[11] and the results were expressed in reference to the international standard for anti-*Toxoplasma* serum. Serum samples with less than 5 IU/mL were considered negative.

The IgM-IFAT was employed as described by Remington et al,[13] using fluorescein conjugated antihuman IgM specific for μ-chain (Dakopatts A/S, Denmark).

Serum IgM, IgA, and IgG levels and C-reactive protein concentrations were measured by single radial diffusion, employing commercially available antibody agar plates.

Specific antibody load was defined as the number of international units of *Toxoplasma* antibodies per milligram of IgG.[14] The value was estimated separately for each serum sample.

The cell-mediated immunity (CMI) was measured with use of a micromodification of the in vitro lymphocyte stimulation test (LST), with a lysate of *T gondii* (32 μg/mL of protein) as antigen.[15] The mononuclear cells were isolated from heparinized blood samples by centrifugation and cultured in medium RPMI 1640 containing 20% pooled human AB serum. Cultures containing 250,000 cells and 250 μL of medium were stimulated by 10 μL of antigen and treated as previously described.[16] Harvesting was performed on the sixth day with fiberglass filters. The incorporation of tritiated thymidine, which had been added 18 hours before the harvest, was measured by a liquid scintillation counter. A positive control was included in every test run, as well as control cultures without antigen. The degree of stimulation (stimulation index [SI]) was given as the ratio between the increment in counts per minute in the stimulated culture and the cpm in the unstimulated culture. An SI greater than 2 was considered positive.

Demonstration of Parasites

Amniotic fluid, cord blood, cord tissue, and placental tissue were examined for parasites. Amniotic fluid was centrifuged at low speed and the supernatant was used. Cord blood was allowed to clot. Placental tissue (50 g) was homogenized in a mortar with the addition of 2 mL of sterile isotonic saline solution containing 100 IU/mL of penicillin and 100 μg/mL of streptomycin per gram. Drop preparations were made for microscopical examinations. For animal inoculation, the placental tissue was digested with a solution containing 0.25 g trypsin.[17]

The indirect fluorescent antibody test for detection of parasites was performed as described earlier.[18] Approximately ten drop-preparations from each sample were studied. The test was considered positive if at least three parasites were observed in each preparation of the sample.

Animal Inoculation

The test suspensions (supernatant of the amniotic fluid, digested placental homogenate, cord blood clot) were mixed with penicillin, 100 IU/mL, and streptomycin, 100 μg/mL; 0.5 mL was injected intraperitoneally into five DT-negative female mice. After six weeks, the mice were bled and killed. A DT was performed and suspensions of brain were examined microscopically for cysts.

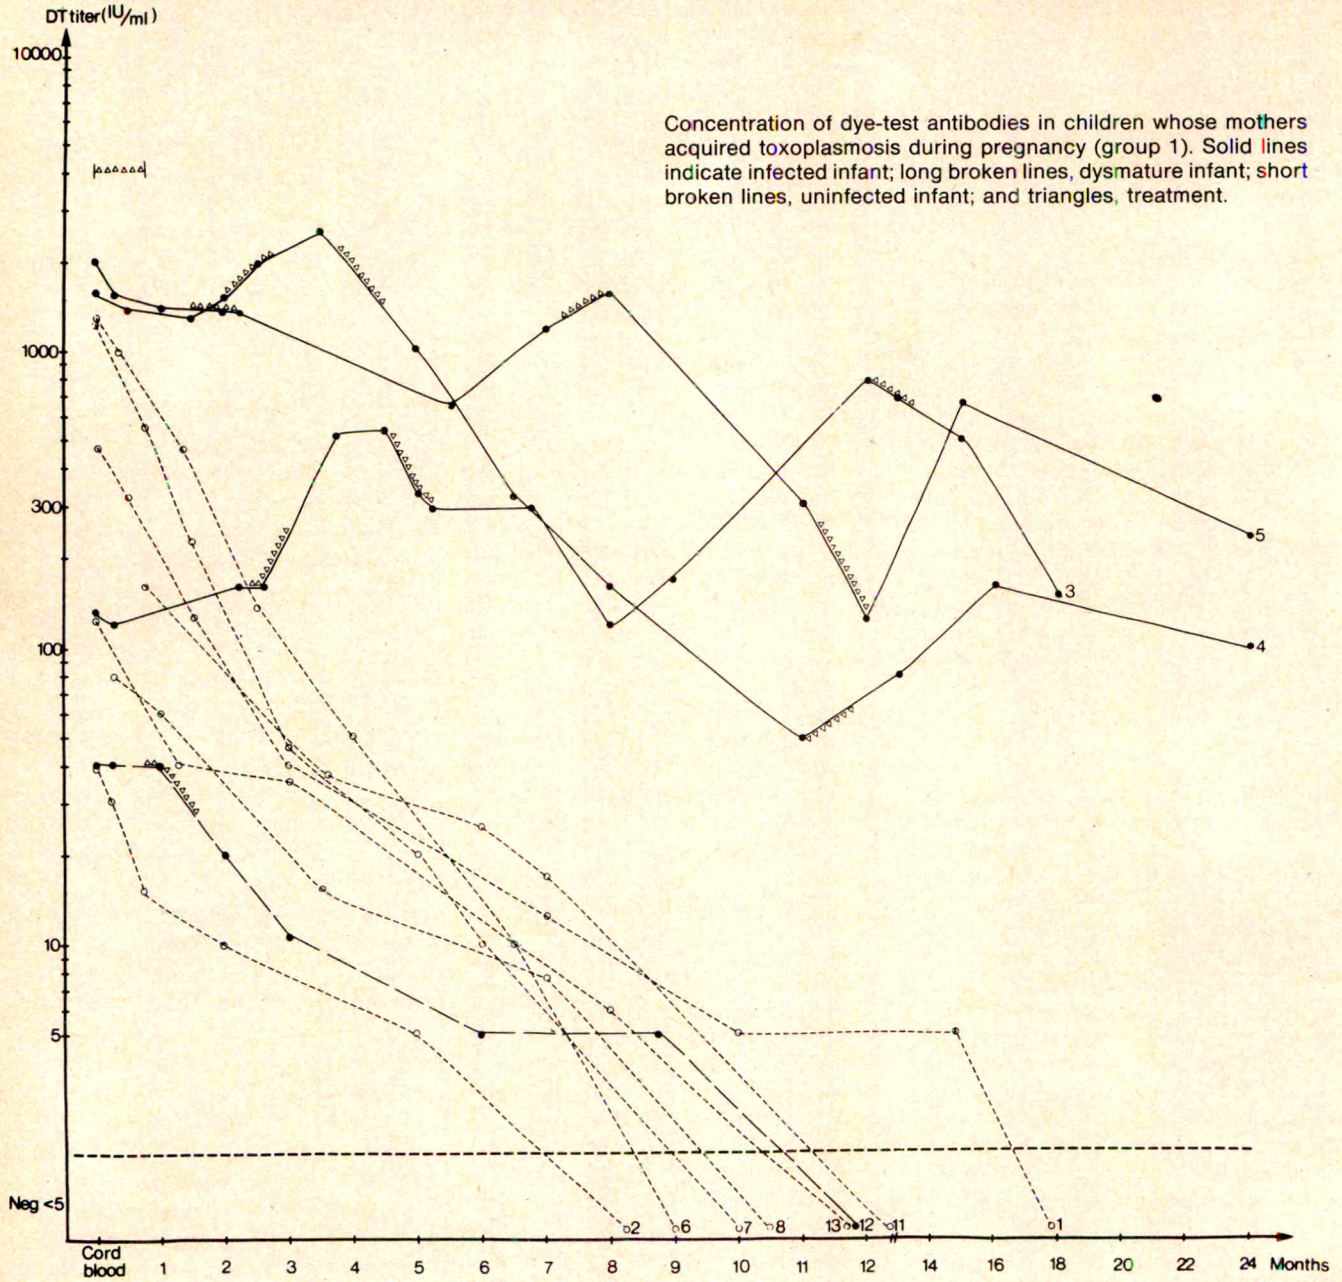
RESULTS

Neonatal Evaluation

Clinical Examinations.—The deliveries of the 52 children were normal and occurred approximately at term. One child (patient 12) was born dysmature, weighing 2,130 g after 40 weeks' gestation. Weights of the other infants were within normal range (means, 3,540 g in group 1, 3,600 g in group 2, and 3,580 g in group 3). Head circumferences were within normal limits (35 ± 2 cm), and Apgar scores recorded one minute after delivery were in all cases 7 or greater. In the neonatal period, hepatosplenomegaly was observed in one infant (patient 5), and another (patient 2) showed hyperbilirubinemia and icterus. Funduscopic examinations of the neonates demonstrated no eye abnormalities, and roentgenograms did not show intracerebral calcifications or other abnormalities of the skull.

Serologic Tests.—The concentrations of DT antibodies in cord blood ranged from 40 to 2,050 IU/mL in group 1 (Figure). Four children (patients 4 through 7) had titers above 1,000 IU/mL. The levels of groups 2 and 3, however, were within the range of 40 to 420 IU/mL. The titers were almost identical to maternal values except in those infants in group 1 whose mothers were in the acute stage of infection at the time of delivery (DT > 300 IU/mL; IgM-IFAT, positive). The IgM-IFAT was negative in all samples of cord blood. The concentration of cord IgM, however, was found to be elevated in three children of group 1 (patients 1 and 4, 0.23 mg/mL; patient 5, 0.49 mg/mL), while the mean values of the remaining children in group 1 and the children in the two other groups were 0.15 mg/mL. The concentrations of the cord IgA were, in most cases, unmeasurable (ie, < 0.01 mg/mL). One infant (patient 4), however, had a value of 0.07 mg/mL.

Parasite Identification.—In three infants (patients 3, 4, and 5), parasites could be demonstrated in the amniotic fluid and/or the placental tissue; thus,



Concentration of dye-test antibodies in children whose mothers acquired toxoplasmosis during pregnancy (group 1). Solid lines indicate infected infant; long broken lines, dysmature infant; short broken lines, uninfected infant; and triangles, treatment.

these three children were unequivocally infected with *T gondii* in utero. In infants 3 and 5, the placentas were found to contain parasites both by inoculation and by immunofluorescence; in infants 4 and 5, the amniotic fluid was parasite-positive by inoculation. In the samples of cord blood and umbilical cord tissue, however, parasites could not be demonstrated. In every case, the amniotic fluid contained DT antibodies, but in much smaller concentrations (range, 10 to 150 IU/mL) than in the cord blood. No IgM-IFAT antibodies were detected in the amniotic fluid.

Treatment.—The prophylactic treatment with spiramycin during the neonatal period was well tolerated, with no adverse effects noted. The three definitely infected infants and one infant (patient 12) with a suspected infection, which later could not be confirmed, received treatment with pyrimethamine, sulfadiazine, and folic acid (Figure). The children tolerated the drugs well. The weekly monitoring of blood cell and platelet counts gave no indication of bone marrow depression.

Long-term Evaluation

Clinical Examinations.—None of the children had clinical manifestations (neural, ocular, cerebral) of congenital toxoplasmosis. The motor and mental development in the three infected children appeared to be normal, but two of them (patients 4 and 5) have

had febrile convulsions, but with normal electroencephalograms.

Serologic Tests.—The serum DT levels measured during the first two years in group 1 infants are shown in the Figure. The amount of DT antibodies in the neonatal period was lower than in cord blood. In the dysmature infant (patient 12), however, the DT titer remained elevated in the blood samples collected during the first month after delivery. In the uninfected children, the titers then decreased exponentially, showing a reduction of about 50% per month, and becoming negative usually between 8 and 18 months of life. In the three infected infants, the *Toxoplasma* antibodies persisted and a DT concentration of 150 to 300 IU/mL was measured at the age of 2 years.

The IgM-IFAT remained negative in all infants. One of the infected children (patient 5) had excessive IgM production during his first year, while the synthesis of IgM and IgA of the two others did not differ from that of the uninfected children. As expected, the IgG concentration decreased markedly after birth, reaching minimum levels before 6 months of age, then showing a steady increase. Consequently, the specific antibody load was found to increase in the postnatal period in the three infected infants and in the dysmature infant (patient 12). In the former, the values thereafter remained unabated, while the latter infant's antibody load decreased rapidly in similarity to that observed in the uninfected children.

Cell-Mediated Immunity.—The specific CMI was found to be negative (SI, < 2) in samples obtained from two of the infected infants (patients 3 and 5) during their first year. (Patient 4 was also tested, but the results were discarded because of technical difficulties.) At 12 months of age, the responses in all three infected children were weakly positive (SI, 3 to 4). Thereafter, the stimulation increased markedly, giving SI values between ten and 45 during the second and third years. Among the repeatedly tested uninfected infants, one child showed a weakly positive LST response (SI, 2) at 1½ years of age, while the other children remained LST-negative.[15]

COMMENT

Children in all of the risk groups developed normally throughout the period of observation, and no clinical manifestations of congenital toxoplasmosis were observed. The serologic follow-up examinations, however, showed that three children had been infected, and the diagnosis was confirmed by recovery of parasites from either the placenta or the amniotic fluid. The fact that these three children all belonged to group 1 strongly supports the generally accepted theory that congenital toxoplasmosis occurs only in those pregnancies in which the woman acquires the infection during her gestational period.[14]

The serologic examinations of cord blood appeared to be of less value in determining the diagnosis. The presence of specific IgM antibodies represents a reliable indicator of congenital toxoplasmosis,[4,19] but in the present study the *Toxoplasma* IgM-IFAT was negative in the cord blood as well as in the subsequent blood samples from the infected children. This lack of diagnostic sensitivity has also been reported in other investigations.[14,20] Quantitative determinations of cord IgM and IgA levels have been proposed as an alternative method in screenings of congenital toxoplasmosis,[4,21] and in two of the infected infants, the cord concentrations of these immunoglobulins were found to be elevated.

The DT titers of the uninfected children decreased gradually by age and became negative between 8 and 18 months of age, depending on the cord DT level (Figure). The reduction in titers corresponded to the expected rate of decline of maternal antibodies in the infant. In the infected children, the concentration of DT antibodies showed a transient minor decrease and then remained elevated throughout the period of observation. On the basis of the DT curves, therefore, the diagnosis became evident between one and three months after the delivery. At an earlier stage, ie, during the first postnatal weeks, estimations of the specific antibody load suggested the diagnosis.

Whereas the immune response to *T gondii* is both humoral and cell mediated, CMI is not transferred from mother to fetus during pregnancy. Hence, demonstration of cellular immunity might serve as a supplementary diagnostic test of congenital infection. In the present study, only the infected infants were strongly positive in the in vitro lymphocyte stimulation test. However, since the development of the CMI became evident after a lag period of several months—a phenomenon that is also observed in adults with acquired toxoplasmosis—a negative test during the first year may not exclude the diagnosis, while a positive test may be indicative.

Child 12 actually represented a diagnostic problem. She was born dysmature; in the neonatal period, the DT titers were stable and the antibody load increased. Thereafter, a marked decrease in the DT titer and the antibody load were observed. No parasites were demonstrated and the CMI remained negative. It is possible that the mother had been infected during the first trimester, and that the maternal infection affected placental development and function, resulting in inadequate fetal growth.

We thought that all infants in the high-risk group required prophylactic therapy (spiramycin). No adverse effects were observed, and the treatment did not seem to influence seroreactivity. In the infected infants, pyrimethamine/sulfadiazine treatment was started as soon as the diagnosis was established. This treatment did not appear to alter the immune responses, as judged by the DT curves and the development of CMI. None of these children had clinical symptoms of congenital toxoplasmosis.

It is of particular note that parasites could be recovered not only from the placenta, as previously reported,[3,22] but also from the amniotic fluid. This finding may provide a future method of diagnosis, even *ante*natally. In suspected cases, amniocentesis might be performed and the fluid examined for content of *T gondii*.

The Department of Pediatrics, Rikshospitalet, University of Oslo, assisted in various ways with this study.

Chemoprophylaxis for *Pneumocystis carinii* Pneumonitis

Outcome of Unstructured Delivery

Richard B. Wilber, MD; Sandor Feldman, MD; William J. Malone, MD; Michael Ryan, DO; Rhomes J. A. Aur, MD; Walter T. Hughes, MD

• **Sulfamethoxazole-trimethoprim was administered prophylactically to 786 patients judged to be at sufficient risk for development of *Pneumocystis carinii* pneumonitis. The selection of patients, administration of the agents, and surveillance for compliance were the responsibility of the attending oncologists rather than specialists in infectious diseases, as in an earlier trial at this center. The recommended dosage was trimethoprim, 150 mg/sq m/day, and sulfamethoxazole, 750 mg/sq m/day. Over a three-year study period, nine cases of *P carinii* pneumonitis occurred at this institution, with none attributable to drug failure. Adverse reactions, skin rashes mainly, were noted in 43 patients, and one patient died with Stevens-Johnson syndrome. These results confirm the efficacy of sulfamethoxazole-trimethoprim in preventing *P carinii* pneumonitis in childhood cancer patients and illustrate the feasibility of large-scale unstructured delivery of the combination to patients with malignant diseases frequently associated with this pneumonia.**
(*Am J Dis Child* 134:643-648, 1980)

Reprint requests to Infectious Diseases Service, St Jude Children's Research Hospital, 332 N Lauderdale, Memphis, TN 38101 (Dr Wilber).

Prophylactic use of antimicrobial agents has been a persistently appealing, though seldom successful, strategem for the prevention of infectious diseases.[1] Hughes et al,[2] however, have shown that sulfamethoxazole-trimethoprim is highly effective in the prevention of *Pneumocystis carinii* pneumonitis. In their double-blind placebo-controlled trial conducted at this center for patients at high risk for *P carinii* pneumonitis, a closely supervised, structured system of drug delivery was used, with a full-time monitor to ensure patient compliance and verification of drug-induced adverse reactions. Patients received the drug continuously throughout the duration of anticancer therapy. Dosages were trimethoprim, 150 mg/sq m/day, and sulfamethoxazole, 750 mg/sq m/day, given in two divided doses. Recently, Harris et al[3] have confirmed the efficacy of sulfamethoxazole-trimethoprim prophylaxis administered according to a similar regimen.

Even when a drug is proved effective for prophylaxis, its delivery by the physician and acceptance by the patient may be inadequate. Thus, despite the known value of sulfamethoxazole-trimethoprim prophylaxis, a pragmatic question remained: what impact would use of this drug combination have on the overall incidence of *P carinii* pneumonitis when patient selection, drug administration, and surveillance of compliance were the responsibility not of a full-time monitor but of the attending oncologist and the patient or parent, as would be the case in most settings other than a cancer research treatment center? Accordingly, an open study with an unstructured delivery system (ie, no full-time monitor) was undertaken to evaluate the effect of these variations in protocol design. A second purpose of the study was to provide a means for the possible elimination of this disease in our patient population.

SUBJECTS AND METHODS

Selection of Patients and Calculation of Risk

From November 1976 through December 1979, sulfamethoxazole-trimethoprim was administered to all patients at St Jude Children's Research Hospital who, in the judgment of the attending oncologists, were at sufficient risk for *P carinii* pneumonitis. Data on which to base this judgment were provided at the outset of the study by the Infectious Diseases Service. Projected risk was based on retrospective assessment of the incidence of *P carinii* pneumonitis in this institution as a whole, and within specific tumor and therapy groups during the years 1970 through 1975, ie, before the general use of sulfamethoxazole-trimethoprim prophylaxis. Previously published and unpublished studies had

related the risk of *P carinii* pneumonitis at this institution to both the type of malignancy and the intensity of administered chemotherapy.[4] However, in determining the population at risk for *P carinii* pneumonitis, ie, those eligible to receive sulfamethoxazole-trimethoprim, the intensity of administered drug therapy was not considered. All patients whose tumor types had been associated with *P carinii* pneumonitis at this center were included in the population at risk and were eligible for sulfamethoxazole-trimethoprim prophylaxis during their anticancer therapy.

Annual institutional attack rates for *P carinii* pneumonitis were calculated by dividing the number of cases in a given year by the number of patients who had only those tumor types and who had attended the hospital in that year. *Pneumocystis carinii* pneumonitis-associated tumor types and attack rates for the years immediately prior to this study are given in Table 1. This method results in a broad population base and includes patients with varying risk for *P carinii* pneumonitis, but it provides the benefit of prophylaxis to all who may be at risk as well as the most consistent inclusive population in which to analyze the year to year changes in the overall institutional incidence of *P carinii* pneumonitis.

Drug Administration and Monitoring

Informed consent was obtained for all patients who received prophylaxis. The recommended dosage was trimethoprim, 150 mg/sq m/day, and sulfamethoxazole, 750 mg/sq m/day. The combination was administered orally in tablet or suspension form in two equal doses given at 12-hour intervals. No more than 320 mg of trimethoprim and 1.6 g of sulfamethoxazole were given in any 24-hour period. Each tablet contained 80 mg of trimethoprim and 400 mg of sulfamethoxazole. The suspension contained 40 mg of trimethoprim and 200 mg of sulfamethoxazole per 5.0 mL. Since in the successful preceding structured study, prophylaxis was given continuously throughout anticancer therapy, this approach was also recommended for the current study. Termination of prophylaxis was advised only for unacceptable adverse reactions, onset of *P carinii* pneumonitis while receiving sulfamethoxazole-trimethoprim prophylaxis, or after completion of one month of prophylaxis following successful termination of anticancer chemotherapy. Records of sulfamethoxazole-trimethoprim dispensed to patients were maintained in the computer files of the hospital pharmacy.

The absence in the previous structured study of any noticeable effect on the recipients' tolerance for anticancer chemotherapy indicated that planned modification of chemotherapy would not be necessary. Also, in view of the low anticipated rate of adverse reactions and since this was a study of an "unstructured" delivery system, reporting of side effects depended on the assessment by the attending oncologist of the relationship of the reaction to sulfamethoxazole-trimethoprim and its importance. These side effects were identified at the completion of the study by a computer-assisted search of the medical records for any side effects attributed to sulfamethoxazole-trimethoprim.

*Data provided to attending physician.

Identification and Management of Patients With *P carinii* Pneumonitis

The diagnosis of *P carinii* pneumonitis was made only when typical *P carinii* organisms were identified by either Gomori's methenamine silver nitrate or toluidine blue-0 staining of pulmonary aspirates or lung specimens obtained before or after death. Since the mortality of untreated *P carinii* pneumonitis is about 100% in immunosuppressed patients,[5] cases not recognized clinically were expected to be detected by autopsy studies. The clinical management of those cases of *P carinii* pneumonitis that occurred during the study followed previously published guidelines,[6] and in those cases the choice of pentamidine or sulfamethoxazole-trimethoprim for antipneumocystis therapy was determined by best clinical management.

Evaluation of Prophylaxis Success

Comparison of annual attack rates of *P carinii* pneumonitis at this center prior to and after initiation of this study were used to measure the success of this method of delivery and to judge whether the goal of the study, elimination of *P carinii* pneumonitis as a cause of morbidity and mortality in patients at this center, was realized. Each case of the pneumonia was considered a failure of prophylaxis. Failures were attributed either to drug inefficacy if *P carinii* pneumonitis developed while receiving the recommended dose of sulfamethoxazole-trimethoprim, or to inadequate drug delivery if the patient was not receiving the combination or was receiving a lower than recommended dosage.

RESULTS

Patients Chosen to Receive Prophylaxis

Each year during the study period, roughly 1,000 patients per year were determined to be at risk for *P carinii* pneumonitis, based on previous association of their tumor type with *P carinii* pneumonitis. Of these patients, those not chosen to receive prophylaxis were judged to be at too low a risk by the attending oncologists, who considered the intensity of administered therapy, the age of the patient, and the phase of therapy as well as *P carinii* pneumonitis-associated tumor types to be important determinants of risk. With these combined criteria for risk, the oncologists entered 786 patients in the study from

November 1976 through December 1979. Of these patients, not all were given prophylaxis throughout the duration of their chemotherapy. Some received prophylaxis only during phases of therapy associated with a perceived high risk for *P carinii* pneumonitis.

The majority of the patients who received prophylaxis (618/786) had acute leukemia. With the exception of 201 of these who were initially treated in the Total Therapy for Acute Childhood Lymphocytic Leukemia Study IX (the Total IX study) (unpublished study, 1979, R. J. A. Aur, MD, M. S. Verzosa, MD, H. O. Hustu, MD, J. V. Simone, MD), patients with acute leukemia entered in this study received sulfamethoxazole-trimethoprim continuously during chemotherapy. Those in the Total IX study received prophylaxis only during a five- to seven-month period after diagnosis and initiation of therapy. This time was perceived to be an especially high-risk period because, prior to availability of sulfamethoxazole-trimethoprim, six of the first 92 patients in the Total IX study had *P carinii* pneumonitis within three months of diagnosis.[7]

Continuation phase therapy with mercaptopurine daily and methotrexate weekly had been previously associated with about a 2% risk for *P carinii* pneumonitis.[4] For patients treated according to the Total IX study regimen, prophylaxis was discontinued after three to five months of continuation phase therapy because of low perceived risk. Treatment with sulfamethoxazole-trimethoprim was reinstituted only if therapy was intensified because of relapse of their leukemia. This practice was modified in January 1979. After that time, new patients entered into the Total IX study received sulfamethoxazole-trimethoprim continuously, and prophylaxis was reinstituted for those Total IX study patients who were still receiving continuation therapy. The rationale for this change will be mentioned in the "Comment" section.

Patients who entered this study with malignancies other than leukemia also received sulfamethoxazole-trimethoprim continuously during chemotherapy, with the exception of patients with neuroblastoma. They received sulfamethoxazole-trimethoprim only if they were less than 1 year of age, a period of perceived high risk for these patients.

Frequency of *P carinii* Pneumonitis

Despite a continued increase in the number of patients at risk, the annual rate of *P carinii* pneumonitis at this center decreased during this study (Figure). In 1977, three cases of *P carinii* pneumonitis developed among 994 patients (0.3%) at risk. In 1978, five cases of *P carinii* pneumonitis occurred among the 1,120 patients who formed the population at risk (0.45%); in 1979, one case occurred among 1,200 patients (0.08%) considered to be at risk.

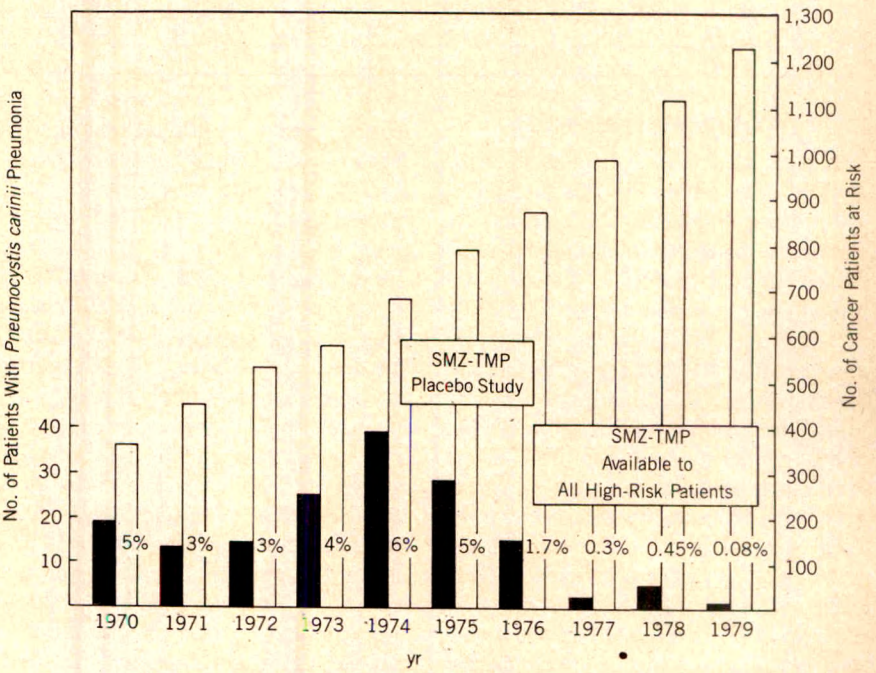
The clinical details of cases of *P carinii* pneumonitis that developed during this study are summarized in Table 2. All subjects except patient 1 were in remission from their primary disease when pneumonitis developed. The case fatality rate remained at about 20% (2/9).

No cases of *P carinii* pneumonitis were discovered at autopsy that had not been apparent before death. During the course of this study, from November 1976 through December 1979, a total of 433 patients at this center died; of this number, 215 (50%) had autopsies. Within the subpopulation of 786 patients entered in this study, 253 died and 128 (51%) had autopsies. Only case 2 (Table 2) had histologic evidence of *P carinii* pneumonitis at autopsy.

Categorization of Failures of Prophylaxis

None of these nine cases could be attributed to the inefficacy of sulfamethoxazole-trimethoprim, as they developed when patients either were not receiving the combination or, as in case 1, were receiving a presumably inadequate dose and hence were considered the result of failure of drug delivery.

No cases occurred in patients excluded from our defined population at risk, ie, in noncancer patients or in patients whose tumor types had not been previously associated with *P carinii* pneumonitis.



Impact of sulfamethoxazole-trimethoprim (SMZ-TMP) prophylaxis on incidence of *Pneumocystis carinii* pneumonitis at St Jude Children's Research Hospital, Memphis. Open bars represent number of active patients at risk with eligible tumor type who attended hospital each year; solid bars denote patients who acquired *P carinii* pneumonitis. Scale for solid bars is ten times as great as for open bars. Availability of chemoprophylaxis for all patients at risk did not begin until November 1976.

Table 3.—'Drug Related' Adverse Reactions in 786 Patients

Type of Reaction	No. of Patients	No. of Fatalities
Dermatologic		
Mild skin rashes	24	0
Erythema multiforme	2	0
Stevens-Johnson syndrome	1	1
Gastrointestinal	2	0
Hematologic	14	0

Adverse Reactions

A review of the medical records of the patients entered in this study for reference to side effects ascribed to sulfamethoxazole-trimethoprim disclosed 43 patients (5.4%) with presumed adverse reactions (Table 3). Twenty-four patients had mild skin rashes, often a pruritic, macular papular rash on the face and upper extremities. The relationship to sulfamethoxazole-trimethoprim administration was unclear, however, as the rash resolved in all but three cases with no recurrence when sulfamethoxazole-trimethoprim was reinstituted. Because of their greater severity, two cases of erythema multiforme and one case of Stevens-Johnson syndrome are tabulated separately. The latter accounted for the only "drug related" fatality (0.12%). Gastrointestinal distress occurred in two patients and was primarily manifested as vomiting after taking sulfamethoxazole-trimethoprim. Hematologic abnormalities, neutropenia and anemia, were related to sulfamethoxazole-trimethoprim administration in 14 patients. The drug therapy was discontinued in all cases. In seven of these 14 cases, drug administration resumed when the patients' neutrophil counts had recovered and no further occurrence of neutropenia was demonstrated. The remaining seven patients had recurrences of either anemia or neutropenia when sulfamethoxazole-trimethoprim was readministered, and use of the drug combination was discontinued. However, one of this latter group had *P carinii* pneumonitis 7¼ months after administration of sulfamethoxazole-trimethoprim was stopped. After recovery from *P carinii* pneumonitis, sulfamethoxazole-trimethoprim was reinstituted simultaneously with leucovorin. He tolerated this regimen without further anemia or neutropenia.

COMMENT

The outcome of this study confirms an earlier report of the efficacy of sulfamethoxazole-trimethoprim in the prevention of *P carinii* pneumonitis,[2] and demonstrates the feasibility of large-scale unstructured delivery of prophylaxis to patients in well-defined tumor categories, selected because of their previous association with *P carinii* pneumonitis. The most important factor contributing to the continued decrease in both the absolute number of cases of *P carinii* pneumonitis and in the attack rate (Figure) appears to be the introduction of sulfamethoxazole-trimethoprim prophylaxis. This conclusion and the data on which it is based would be open to question if during this study period we had failed to detect cases of *P carinii* pneumonitis that occurred, or if changes in intensity of chemotherapy administered to the majority of patients had reduced the susceptibility of the population to *P carinii* pneumonitis. With regard to the failure to detect cases of *P carinii* pneumonitis, physicians at this center and cooperating local physicians caring for these patients are familiar with and

alert for the presentation of *P carinii* pneumonitis. No patient at this center receives pentamidine or *therapeutic* (anti-*P carinii* pneumonitis) dosages of sulfamethoxazole-trimethoprim (trimethoprim, 20 mg/kg/day, and sulfamethoxazole, 100 mg/kg/day[6]) for any reason other than an histologically confirmed diagnosis of *P carinii* pneumonitis. If this pneumonia remains untreated in a patient whose immunity is blunted by cancer or anticancer therapy, there is virtually 100% mortality.[5] Therefore, any undetected cases of *P carinii* pneumonitis would be untreated, and would be detected at autopsy, where processing of lung tissue with Gomori's methenamine silver stain was included in the standard autopsy protocol. Although the autopsy rate at this center during this period had declined to approximately 50%, it is unlikely that many cases of this pneumonia were undetected.

The intensity of chemotherapy administered to patients at this center during this study, at least for those patients at highest risk for *P carinii* pneumonitis, ie, those with acute leukemia, was essentially as intensive as that administered during the years 1970 through 1971. During that period, there were fewer patients at risk per year—357 and 452, respectively—and more cases of *P carinii* pneumonitis—18 cases in 1970 and 12 cases in 1971 (Table 1). In light of these considerations, our data indicate that the reduction of both the absolute number of cases and the attack rate of *P carinii* pneumonitis at this center is due primarily to the introduction of sulfamethoxazole-trimethoprim prophylaxis.

In addition to the elimination of *P carinii* pneumonitis among patients at this center, a further objective was to assess the feasibility of an unstructured delivery of prophylaxis, including the designation of an at-risk population based on previous *P carinii* pneumonitis-tumor type association. The fact that no cases occurred outside of the population defined to be at risk and eligible for prophylaxis demonstrates that this is an acceptable method for defining patients at risk, although we realize it does include patients at low risk and we caution that the specific tumor groups defined to be at risk apply only to this center. Physicians at other centers should evaluate the risk of *P carinii* pneumonitis for their patients based on observed frequencies of the disease at their institutions.

The occurrence of nine cases of *P carinii* pneumonitis during the study among patients eligible for prophylaxis prompted examination of these failures of drug delivery. Several explanations for these failures were apparent. As might be expected, occasional eligible patients were inadvertently not entered into this study and thus did not receive sulfamethoxazole-trimethoprim prophylaxis (patient 2 in Table 2). Also, the drug was occasionally prescribed in less than the recommended dosage (patient 1). Some patients had unacceptable adverse reactions, resulting in withdrawal of chemoprophylaxis (patient 7). Patient 3 was receiving antileukemic treatment as specified in Total Therapy Study VIII, group C, in which the calculated risk of pneumonitis was 2.5%.[4] This risk was judged to be insufficient by the attending oncologists, so that this patient did not receive the combination. Analysis of the five remaining cases (patients 4, 5, 6, 8, and 9 in Table 2) showed that they were being treated in the Total IX study, and by design of the attending physicians did not receive sulfamethoxazole-trimethoprim after three to five months of continuation phase therapy (mercaptopurine daily and methotrexate weekly) because in a previous study a similarly treated group[4] had had a ≤2% incidence of *P carinii* pneumonitis during continuation phase therapy. However, 3¾ to 7½ months after sulfamethoxazole-trimethoprim therapy was discontinued, *P carinii* pneumonitis developed in these five patients. This experience closely parallels that of Wolff and Baehner,[8] who used a higher dosage of sulfamethoxazole-trimethoprim for a relatively brief time shortly after induction therapy was begun. Among their patients, *P carinii* pneumonitis occurred 128 to 203 days after prophylaxis was discontinued. Such experience emphasizes the uncertainty of determining what level of risk justifies prophylaxis. However, when the frequency of *P carinii* pneumonitis in a particular tumor or therapy category is low, one must carefully weigh the benefits of possible prevention of the infection against the risk of drug toxicity.

Comparison of the incidence of adverse reactions among patients in this study with that in the general population receiving sulfamethoxazole-trimethoprim is difficult. Our patients received sulfamethoxazole-trimethoprim for up to 30 months as opposed to a standard ten-day course of therapy.[9] Moreover, the few children who have received sulfamethoxazole-trimethoprim for a period comparable to that of our patients[10] have not usually received other drugs simultaneously. Detection of adverse reactions to sulfamethoxazole-trimethoprim during this study depended on the assessment by the attending physician of the relationship of any such occurrences to the drug combination, and thus our data reflect only those reactions noted by the attending physician. Also, as is the practice at this center, patients in this study received care as outpatients as often as possible; in addition, many patients received at least part of their care from closely cooperating physicians based close to the patient's home. Despite these limitations on observation, close follow-up is possible as the patients return quite frequently to this center. Also, frequent telephone communication is maintained with assisting local physicians and uniform records are compiled by having local physicians use and forward copies of patient profile sheets provided by this center. These limitations notwithstanding, the incidence of gastrointestinal, hematologic, and dermatologic drug-related side effects in our study group (5.4%) appears slightly higher than that reported for the general population. The occurrence of one "drug related" fatality among 786 patients (0.12%) is higher than would be expected for the general population, in which drug-related deaths have been as low in frequency as 2.5/100,000 to 1/10,000,000 depending on the source.[11,12] Although this death cannot be unequivocally ascribed to sulfamethoxazole-trimethoprim, the

possibility of lethal toxicity weighs against administration of the combination unless the risk of *P carinii* pneumonitis is sufficient. One must realize, however, that even when this infection is promptly recognized and properly treated, its mortality is usually 20% to 30%.[6]

Results of recent in vitro studies of the effect of sulfamethoxazole-trimethoprim on human bone marrow culture suggest that the antifolate activity of the combination may have been responsible for the neutropenia and anemia that developed in 14 of our patients.[13] One of these patients later received leucovorin along with sulfamethoxazole-trimethoprim. The fact that he was able to maintain acceptable neutrophil counts while receiving both drugs adds further substance to this speculation.

The occurrences of *P carinii* pneumonitis during this study and the study by Wolff and Baehner[8] after cessation of prophylaxis was interesting in view of studies by Hughes et al[14,15] and supports the hypothesis that *P carinii* is highly prevalent as an endogenous agent in man and animals and that sulfamethoxazole-trimethoprim merely suppresses and does not eliminate these organisms from the host. This would explain the recurrence of *P carinii* pneumonitis in the immunosuppressed host after short-term prophylaxis. The results of our clinical study are consistent with these experimental data and provide a compelling argument for continuation of sulfamethoxazole-trimethoprim prophylaxis throughout the duration of anticancer chemotherapy. At this center, those patients in the Total IX study who prior to January 1979 did not receive continuous sulfamethoxazole-trimethoprim now receive prophylaxis, as do other patient groups, until one month after cessation of anticancer therapy.

It is likely that the dosage recommended is adequate but very near the threshold for suppression of this infection since slightly lower doses have been associated with *P carinii* pneumonitis (patient 1). Further prophylaxis regimens may benefit from the recently confirmed in vitro propagation of *P carinii*,[16,17] since this capability could permit in vitro determination of a minimal inhibitory concentration range of sulfamethoxazole-trimethoprim for this organism. Determination of serum levels of the drug combination could then be used to adjust the dose of sulfamethoxazole-trimethoprim during prophylaxis.

This study was not designed to evaluate the effect of sulfamethoxazole-trimethoprim on the frequency of bacterial infections among patients who received prophylaxis. However, in a previous study,[2] there was a statistically significant decrease in bacterial infections among recipients of sulfamethoxazole-trimethoprim as compared with a control group who received a placebo. This antibacterial effect may be considered an additional benefit favoring the use of sulfamethoxazole-trimethoprim prophylaxis in cancer patients.

In summary, after a study period of three years, we conclude that sulfamethoxazole-trimethoprim will effectively prevent *P carinii* pneumonitis if administered in an open unstructured delivery system and if given continuously throughout the course of anticancer therapy. Although the data are applicable only to this institution, the methods for establishing the population of patients at risk, ie, retrospective analysis of *P carinii* pneumonitis-associated tumor types, could be used at other institutions with large numbers of childhood cancer patients. The possibility of severe drug-related toxicity should not take precedence over the risk of *P carinii* pneumonitis, although in patients with erythema multiforme or Stevens-Johnson syndrome, we recommend that sulfamethoxazole-trimethoprim therapy be discontinued.

This investigation was supported in part by a grant from Hoffmann-LaRoche Inc., by grants CA 23944, CA 21765, and CA 20180 from the National Cancer Institute, and by ALSAC. Hoffmann-LaRoche Inc. provided the sulfamethoxazole-trimethoprim used in this study.

Paul Bowman, MD, Gary Dahl, MD, Lois Dow, MD, Alexander Green, MD, Ann Hayes, MD, Mahesh Kumar, MD, Sharon Murphy, MD, Judith Ochs, MD, Charles Pratt, MD, Elizabeth Thompson, MD, and Judith Wilimas, MD, participated in this study. Alvin Mauer, MD, and Joseph Simone, MD, provided criticism. John Gilbert helped prepare the manuscript.

Cleidocranial Dysostosis, Severe Micrognathism, Bilateral Absence of Thumbs and First Metatarsal Bone, and Distal Aphalangia

A New Genetic Syndrome

Emilio Yunis, MD, Humberto Varón, MD

• **Five patients from three families have a new genetic syndrome. The features include cleidocranial dysostosis, bilateral absence of the thumbs and of the distal phalanges of the fingers, hypoplasia of the first metatarsus, absence of the distal phalanx and hypoplasia of the proximal phalanx of the big toe, pelvic dysplasia, bilateral hip dislocation, a constant facial dysmorphism with sparse hair, peculiar ears, severe micrognathism, and retracted and poorly delineated lips. The existence of consanguinity in two of the families, both with two affected siblings, as well as the lack of sex predilection, allow us to postulate that this syndrome is inherited in a recessive manner.**

(*Am J Dis Child* 134:649-653, 1980)

During the past four years, we have studied several patients with an interesting constellation of findings in three unrelated families. The uniqueness of our observations and the similarity of the patients have encouraged us to present our findings as a new hereditary syndrome.

REPORT OF CASES

CASE 1.—A female infant was born after a full-term pregnancy and normal delivery. Weight at birth was 2,650 g and length was 48 cm. This was the first pregnancy of a consanguineous marriage. The father was 25 years old and the mother was 20. Familial investigation did not reveal genetic problems (Fig 1). Both parents were healthy and without physical abnormalities. A recent second pregnancy was spontaneously aborted. Fifteen days after birth, the propositus was found to have a head circumference of 37 cm, sparse scalp hair, and a wide and tense fontanelle. A severe micrognathia was observed and the temporomandibular articulation was anteriorly placed. The lips were markedly retracted and poorly delineated and the nasolabial distance was diminished. Glossoptosis made a pharyngeal examination difficult; dental follicles were present. Posterior and low-set ears were square in shape, with a wide concha, prominent anthelix, and absent lower third of the helix, earlobe, tragus, and antitragus. The eyes appeared small and the intercanthal distance was 25 mm. The nostrils were anteverted (Fig 2). Chest examination revealed a thoracic circumference of 29 cm, and absent clavicles and nipples. A cardiac examination did not reveal any pathologic features. The external genitalia were normal. There was agenesis of the thumb, distal aphalangia, and hypoplastic nails in the other fingers. The second fingers also showed absence of the middle phalanges. Bilateral simian creases were observed. The feet showed agenesis of the great toe and hypoplastic nails. In both hands and feet, the fingers appeared pointed (Fig 3). Both hips were dislocated. The patient died 22 days after birth; an autopsy was not performed. Roentgenologic findings, summarized in Table 1, included a skull with craniofacial disproportion due to hypoplastic facial bones and macrocrania, micrognathia, and glossoptosis. In the vault, especially over the parietal bones and the anterior and posterior fontanelles, the ossification pattern was delayed (Fig 4). The thorax showed bilateral agenesis of the clavicle (Fig 4) and absence of the ossification centers of the sternum. Both hands showed striking alterations, with bilateral absence of all the components of the axial finger and distal aphalangia for the rest of the fingers; the middle phalanx of the second finger was hypoplastic in the right hand and absent in the left (Fig 4). Hypoplastic first metatarsal bones and hypoplastic proximal phalanges of the big toes were found in both feet. Pelvic involvement included flattened acetabuli and less than normal transverse iliac diameter. Bilateral hip dislocation was found.

Patients 2 and 3 were products of the second and third pregnancies from a nonconsanguineous marriage; the father was 30 and the mother was 27 years old. Family history was negative for genetic problems (Fig 1) and both parents were healthy with no physical abnormalities. The first pregnancy produced a boy who developed normally but died of meningitis at 5 months of age.

CASE 2.—This boy was the product of a full-term pregnancy and normal delivery. He lived only one day, and no postmortem examination was done. His physical appearance was remarkably similar to that of

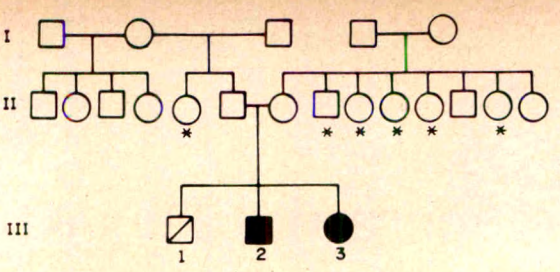
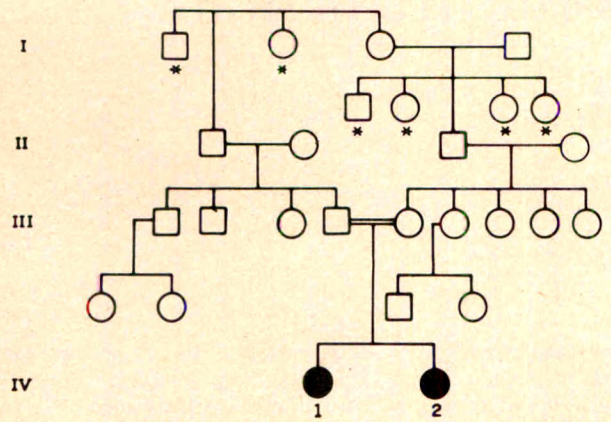
Family 1



Family 2



Family 3

* Normal descendants

Fig 1.—Pedigree of three studied families. Consanguinity exists in families 1 and 3. Genetic abnormalities could not be recorded in three or four generations.

Fig 2.—Case 1. Frontal (top left) and lateral (top right) views. Case 3. Frontal (bottom left) and lateral (bottom center) views. Case 4. Lateral view (bottom right). Craniofacial characteristics are clearly visible: craniofacial disproportion, sparse hair, peculiar ears with wide concha, absent tragus, antitragus, and earlobe, poorly defined lips, and severe micrognathia.

Birth weight was 2,500 g, length was [illegible] m, head circumference was 34 cm, and intercanthal distance was 25 mm. His cry was weak. The skull showed sparse hair and a wide fontanelle. Severe micrognathism and anterior temporomandibular articulation were observed. The nasolabial distance was diminished. Posterior and low-set ears showed a prominent anthelix with absence of the lower third of the helix, earlobe, tragus, and antitragus. The nose showed anteverted nostrils. Chest examination revealed a thoracic circumference of 30 cm and absent clavicles. Cardiac examination findings were normal. External genitalia had a male appearance with ectopic testes and micropenis. Bilateral hip dislocation was found. Hands and feet showed the same abnormalities as seen in patient 1, with bilateral thumb agenesis and distal aphalangia in all the fingers. Bilateral simian creases were present. The feet showed agenesis of the big toes. In both hands and feet the digits appeared pointed, with hypoplastic nails. No roentgenologic examination and no laboratory investigations were done in this case.

Case 3.—This female infant was the product of a full-term pregnancy. Her birth weight was 2,300 g, length was 45 cm, head circumference was 34 cm, and intercanthal distance was 24 mm. Clinical examination showed sparse hair, wide fontanelle, diastasis of sutures, depressed temples, and craniofacial disproportion. The facial bones were hypoplastic and a severe micrognathism was observed. The eyes appeared small. The ears, posterior and low set, were remarkably anomalous, with a prominent anthelix and absence of the lower portion of the helix, tragus, antitragus, and earlobe. The nasolabial distance was reduced and a marked labiogingival retraction was present (Fig 2). Chest examination revealed a thoracic circumference of 28 cm and agenesis of both clavicles. Cardiac examination findings were normal. Malformations observed in hands, feet, and pelvis were essentially the same as those observed in cases 1 and 2, including bilateral thumb agenesis, distal aphalangia of the other fingers, bilateral absence of the big toes, and hypoplastic nails in all the fingers (Fig 3, center).

Roentgenologic findings, summarized in Table 1, showed a skull with altered ossification pattern, especially over the parietal bones and the anterior fontanelle; craniofacial disproportion; and hypoplastic facial bones and micrognathia (Fig 4, center left The thorax showed agenesis of the right clavicle and a hypoplastic left clavicle (Fig 4, center right); ossification centers of the sternum were not visible. Both hands had abnormalities, with bilateral absence of all the components of the axial finger and distal aphalangia of the rest of the fingers; the second fingers showed bilateral agenesis of the middle phalanges (Fig 4, bottom left). Hypoplastic first metatarsal bones and hypoplastic proximal phalanges of both big toes were found (Fig 4, bottom right). Pelvic alterations included flattened acetabuli and a small transverse iliac diameter. Bilateral hip dislocation was observed.

Fig 3.—Top, Case 1, view of hands (left) and feet (right). Center, Case 3, view of hands (left) and feet (right). Bottom, Case 4, view of hands (left) and feet (right). Hands and feet, almost identical in all cases, show thumb and big toe agenesis. Hypoplasia of last phalanges and nails as well as pointed appearance of rest of fingers are evident.

Laboratory data for cases 1 and 3 showed normal karyotypes and normal values for the hematologic tests, serum electrolytes, calcium, phosphorus, alkaline phosphatase, urinary calcium, amino acid excretion, and mucopolysaccharide determinations. Autopsy findings were negative, without gross malformations or histologic alterations, with one exception; the brain showed fissures deeper than usual, without alterations of its histologic features.

Patients 4 and 5, both female, were not examined by us. Patient 4 lived 65 days; patient 5, 35 days. The parents' descriptions corresponded to the clinical picture of the other cases, including all the characteristics described in skull, facies, hands, and feet. Birth weight and length were 2,100 g and 43 cm, respectively, for case 4, and 2,300 g and 45 cm for case 5. Both pregnancies were threatened by abortion. The father and mother, aged 27 and 23 years, respectively, are second cousins. No genetic abnormalities were recorded in their families and no physical alterations were present in them (Fig 1). Medical examination of patient 4 revealed a large anterior fontanelle continuous with the posterior fontanelle. An ossification defect of the occipital bone was present. The eyes showed a moderate exophthalmos and hypertelorism. The ears were described as low set and dysplastic. The palate was narrow and arched and a severe micrognathia was seen (Fig 2, bottom). Both hands showed thumb agenesis; absence of the last phalanges and nails was reported for the rest of the fingers. Both feet showed agenesis of the big toe (Fig 3, bottom). Bilateral absence of the clavicle was found. During the clinical

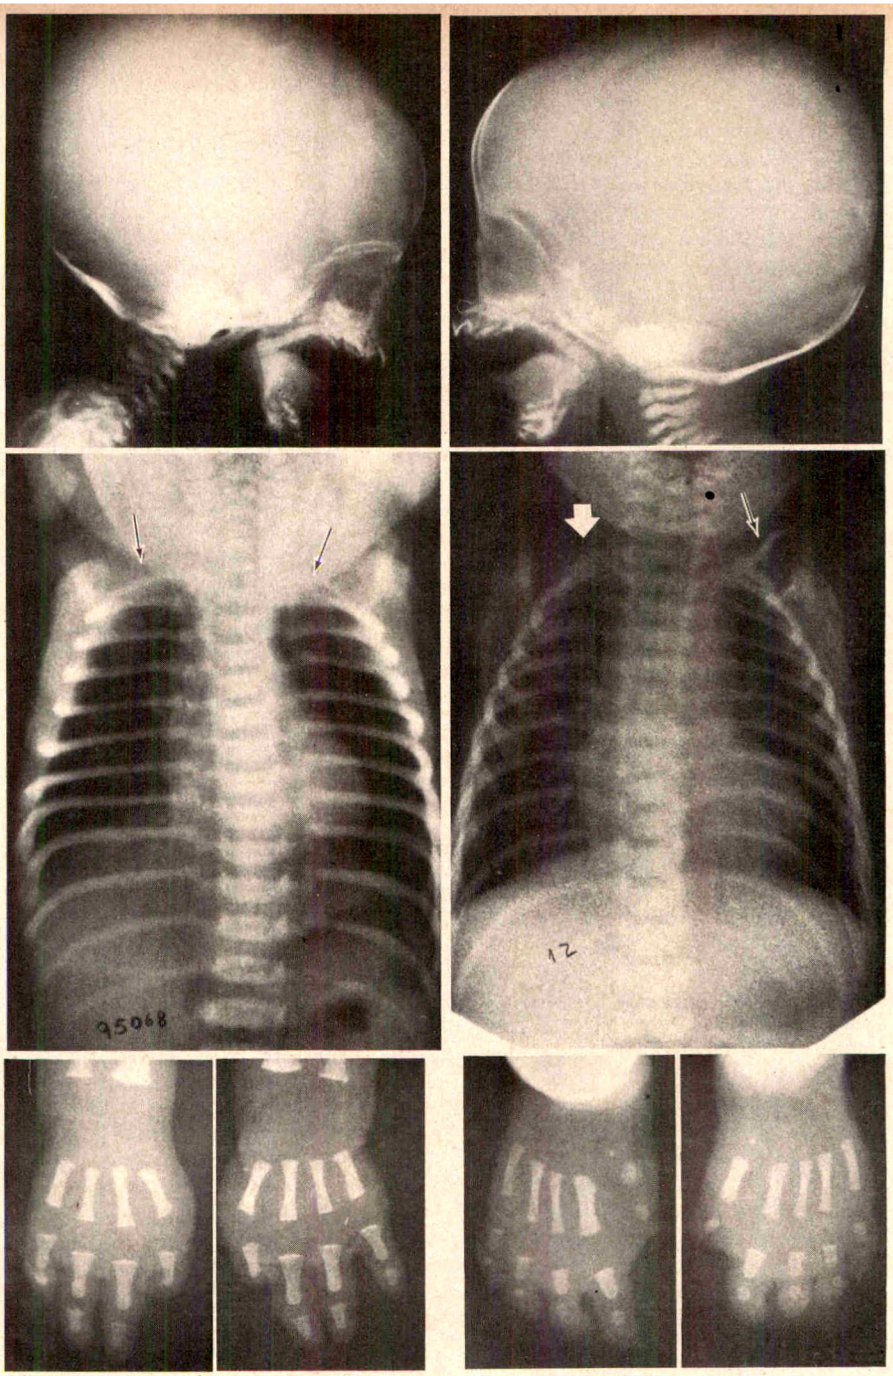


Fig 4.—Roentgenograms showing skull with craniofacial disproportion, hypoplastic facial bones, and micrognathia in patient 1. Note macrocrania and altered ossification pattern with diastasis of the sutures (top left); arrows (center left) show bilateral absence of clavicles, and hands show absence of all components of first fingers and distal aphalangia in rest of them (bottom left). Note that middle phalanx of second finger is hypoplastic in right and absent in left hand. Small differences in relation to (top right, center right, bottom center, and bottom right) are seen in clavicles, where asymetric absence is seen, and hands show bilateral absence of middle phalanges in second fingers. Bottom right, both feet show hypoplastic proximal phalanges in big toes and hypoplastic first metatarsal bone, more severe in right foot.

course, the patient had frequent episodes of respiratory obstruction with cyanosis, requiring intubation until her death. Roentgenologic studies were not done in this case. Autopsy findings included a small thyroid gland, larynx, trachea, lungs, and thymus; the heart was of normal weight and had normal morphologic features. The digestive tract, liver, pancreas, and kidneys were reported to be normal. The brain weighed 300 g, and was normal in shape, but the consistency was harder than usual, with fissures deeper than normal, especially over the frontal lobes. Its histologic features were normal.

Patient 5 was poorly described by the physicians, but the parents said that her physical appearance was similar to that of her sister. Roentgenologic examinations were performed in this case; the results are given in Table 1. Autopsy was not done.

COMMENT

The five patients described herein showed an almost identical clinical and roentgenologic picture. To our knowledge, they represent a syndrome that has not been previously reported. Therefore, we present it as a new hereditary syndrome, the clinical and radiologic characteristics of which are given in Tables 1 and 2.

Although two of the families live in the same general area of the Colombian Andes, in the interior of the country, no known genealogical linkage exists between them. The third family comes from the nothern coast of Colombia, where they have been established for several generations.

The syndrome is present in both sexes, and in two of the families two siblings have been affected; the par-

ents were healthy in all cases, and no abnormal history, either skeletal or metabolic, could be found in their families. Chromosome abnormality was not found in the patients. Two of the families were consanguineous. These considerations allow us to postulate an autosomal recessive inheritance of this syndrome.

Some of the features presented by our patients, mainly the association of micrognathia and glossoptosis, evident in case 1, are components of the Robin anomaly. However, glossoptosis was not a constant finding, and membranous cleft palate was not found in any of the patients. It may be considered that the clinical picture of our patients is somewhat similar to cleidocranial dysplasia, and this is the reason for making some comparisons between these two entities. Cleidocranial dysplasia shows a deficiency in the ossification of the skull with a delay in the closure of the anterior fontanelle, which gives a specific shape to the skull and the forehead. In addition, the hypoplastic maxilla makes for an apparent craniofacial disproportion. The ossification of the clavicles is altered, frequently asymetrically.[1] The features we have mentioned are common to both syndromes, but the differences are remarkable in other aspects: pelvic involvement with delayed ossification of the pubic bone and hypoplasia of the iliac wings are present in cleidocranial dysplasia and they are not in this syndrome. Hand anomalies in cleidocranial dysplasia, which include brachymesophalangia and a characteristic pointing of the terminal tufts of the phalanges with hypoplastic changes evident in the thumbs,[1] are not closely similar to the thumb and first metacarpal agenesis and distal aphalangia that was constant in our five patients. Moreover, the severe micrognathism, peculiar facial dysmorphism, the changes related to the feet, and the recessive genetic pattern are good reasons to differentiate these two entities. Finally, the limited laboratory determinations that we have performed have revealed no biochemical alterations in any of the patients.

Juvenile Chronic Granulocytic Leukemia

Emphasis on Cutaneous Manifestations and Underlying Neurofibromatosis

Jane A. Mays, MD; Robert C. Neerhout, MD; Grover C. Bagby, MD; Robert D. Koler, MD

• Five patients with juvenile chronic granulocytic leukemia are described. Two patients had multiple cafe-au-lait spots compatible with von Recklinghausen's neurofibromatosis, and three had cutaneous xanthomata. Recurrent cutaneous leukemic infiltrates were noted in two patients. The clinical course of all five patients was characterized by recurrent respiratory symptoms and pulmonary infiltrates that responded to antileukemic therapy in three. Chemotherapy controlled the symptoms but did not influence the eventually fatal outcome.

(*Am J Dis Child* 134:654-658, 1980)

The classification of chronic granulocytic leukemia (CGL) in children has been subdivided into juvenile or adult type based on clinical, hematologic, and cytogenetic data.[1-4] The usual criteria for the juvenile type include early age at onset, absence of the Philadelphia chromosome, presence of fetal RBC characteristics, early onset of severe thrombocytopenia, and rapid death in spite of therapy. The adult form tends to occur in older children, is associated with the Philadelphia chromosome, lacks fetal cell characteristics, runs a more chronic course, and responds to therapy with alkylating agents. A recent proposal, based on growth characteristics of peripheral blood cells in culture suggests that the juvenile type of CGL is actually a monocyte-predominant panmyelopathy whereas the adult type is a true granulocytic leukemia.[5-6]

We report five cases of characteristic juvenile type CGL. Two of these five unrelated cases were found to have von Recklinghausen's neurofibromatosis. Three of the five had associated cutaneous xanthomata. The association of juvenile CGL with neurofibromatosis and cutaneous xanthomata is reviewed.

MATERIALS AND METHODS

Hematologic studies, ie, erythrocyte I,i surface antigen determination, and leukocyte alkaline phosphatase, were performed by standard techniques. Fetal hemoglobin value was estimated by the alkaline denaturation method of Singer, and the intracellular distribution of fetal hemoglobin by a modification of the Betke stain.[7,8] Hemoglobin A_2 was quantitated after cellulose acetate electrophoresis[9] and was confirmed by microchromatography on diethylaminoethyl cellulose-52 (DE-52).[10] Red cell carbonic anhydrase B was quantitated by cellulose acetate electrophoresis and by Mancini et al immunodiffusion.[11] The glycine-alanine composition of peptide γ-CG3 was determined by described methods.[12] Cytogenetic studies were by standard methods. Bone marrow specimens were aspirated, and an aliquot was suspended in demecolcine (Colcemid) for two hours before direct preparations were made. Banding was performed by Giemsa and quinicrine mustard techniques.[13,14] Fibroblast karyotypes were prepared by standard methods.[15] Agar bone marrow cultures were performed by the method of Pike and Robinson.[16] The colony stimulating activity (CSA) was determined by described methods.[17]

REPORT OF CASES

The laboratory and clinical observations of the five cases are summarized in Tables 1 and 2.

Case 1.—This male infant was the full-term product of an unremarkable pregnancy and delivery. The newborn period was complicated by group B streptococcus septicemia that responded to antibiotics, phototherapy, and exchange transfusion.

At age 2 months, the patient's WBC count was 30,000/cu mm, with an occasional blast cell seen. The gradual onset of splenic and hepatic enlargement led to hematologic investigation at age 6 months (Table 1). A bone marrow aspirate indicated severe myeloid hyperplasia, but no Philadelphia chromosome was found on direct karyotype preparation. In vitro bone marrow cultures revealed preponderant monocytic differentiation. The serum CSA was greatly elevated. Splenectomy was performed, and extramedullary hematopoiesis was demonstrated in the spleen, mesenteric lymph nodes, and liver. The leukocytosis and thrombocytopenia were unaffected by splenectomy.

The patient had chronic tachypnea and variable interstitial pulmonary infiltrates. At 8 months of age, he had a massive pericardial effusion develop that was relieved by pericardiocentesis. The fluid was sterile and contained no malignant cells. A four-week trial with busulfan therapy resulted in no change in the hematologic values. Prophylactic penicillin G potassium and folic acid were given during the ensuing 19 months. The patient's liver and peripheral lymph nodes enlarged moderately, and chronic respiratory distress continued. The WBC counts remained at about 150,000/cu mm, hemoglobin level, 10 g/dL; and platelet counts, 40,000 to 60,000/cu mm. At age 27 months, he died in bed a few hours after the onset of mild upper respiratory tract symptoms.

Acute pneumonia associated with desquamation of bronchial mucosa was found at autopsy. Marked numbers of atypical inflammatory cells were noted to cuff the peripheral airways. Leukemic infiltrates were noted in all organ systems.

Case 2.—A 2-year-old boy had *Salmonella* enteritis. The patient and his father were known to have neurofibromatosis. Examination showed a chronically ill infant with developmental delay. The liver was palpable 3 cm below the right costal margin and the spleen was palpable 4 cm below the left costal margin. The skin showed multiple facial and scalp xanthomata, multiple truncal cafe-au-lait lesions, and scattered eczematoid lesions on the anterior abdominal wall. Moderate enlargement of the inguinal and submandibular nodes was noted. Results of studies performed at the time of this hospital admission are given in Table 1. Bone marrow aspiration indicated granulocytic hyperplasia with rare megakaryocytes. Marrow karyotype showed 46,XY,Y inversion. The inversion was also present in the patient's skin fibroblast karyotype,

but it was not present in the peripheral blood karyotype of the patient's father. No Philadelphia chromosome was identified. In vitro bone marrow cultures disclosed differentiation that was preponderantly monocytic macrophages. Serum CSA was extremely elevated.

Chemotherapy was deferred because of pertussis-like illness characterized by paroxysms of coughing and by diffuse perihilar interstitial pulmonary infiltrates. The patient had a right flaccid hemiplegia develop during a 24-hour period in conjunction with a WBC count of 116,000/cu mm and a platelet count of 12,000/cu mm. Computerized axial tomography (CT) showed focal edema in the internal capsule, suggestive of hemorrhage.

Treatment was begun with platelet transfusions and combination chemotherapy (prednisone, thioguanine, doxorubicin hydrochloride [Adriamycin], cytarabine [cytosine arabinoside] hydrochloride and vincristine sulfate). After two seven-day courses of therapy, the bone marrow contained abundant megakaryocytes and there was reduction in granulocytic hyperplasia. Spleen size sharply decreased. The peripheral WBC count was now 15,000/cu mm (with occasional blast form), hemoglobin level was 9.7 g/dL, and platelet count was 267,000/cu mm. The patient received an additional five-day course of chemotherapy. Cranial irradiation (2,400 rads) and intrathecal methotrexate sodium (12 mg/sq m on five occasions) were given during a three-week period when the CSF was noted to contain blast cells.

The patient remained relatively well for three months with WBC counts less than 30,000/cu mm. His activity then decreased coincident with severe splenic enlargement. Indurated and erythematous skin lesions were noted on the abdominal wall. These lesions had an elevated circular border with central sparing and measured 4 to 6 cm in diameter. Biopsy specimen showed leukemic infiltrates. The cutaneous infiltrates resolved spontaneously during the next six weeks as the WBC count increased to 80,200/cu mm and the platelet count decreased to 39,000/cu mm.

Treatment with combination chemotherapy was again instituted, and dramatic reduction in spleen size was accompanied by decrease in WBC count and elevation in platelet count. Chemotherapy was administered on an intermittent basis as dictated by the WBC count, splenomegaly, and pulmonary symptoms. A similar but less dramatic response to therapy with azacitidine was noted. His condition remained one of slow deterioration and he died 18 months after diagnosis. No autopsy was performed.

Case 3.—A 4-year 8-month-old boy had an acute respiratory illness. Examination showed a chronically ill appearing boy with protuberant abdomen and scattered petechiae. The liver was enlarged 4 cm below the right costal margin, and a firm spleen was palpable to the iliac crest. Moderate

*CGL indicates chronic granulocytic leukemia; plus sign, present or performed; zero, absent or not performed.

peripheral node enlargement was present. No cafe-au-lait lesions or xanthomata were seen. Results of laboratory studies are given in Table 1. Alpha-chain analysis of the fetal hemoglobin disclosed a glycyl residue at position 136 (G_γ). Bone marrow aspirate was hypercellular, with granulocytic hyperplasia, rare megakaryocytes, and a 46,XY karyotype with no Philadelphia chromosome. Family history was unknown (adopted). Treatment was begun with combination chemotherapy as in case 2, with resultant decrease in marrow cellularity, reduction in peripheral WBCs to 17,000/cu mm, and platelet elevation to 82,000/cu mm. The splenic size decreased greatly within 72 hours of chemotherapy. Chemotherapy was repeated at monthly intervals on three occasions, with resultant temporary response in all variables. His clinical course was complicated by recurrent pulmonary dysfunction resembling acute bronchospasm with shifting atelectasis. This was poorly responsive to antibiotics and bronchodilators but responded to cytoreductive chemotherapy. Five months from initial examination, he had painful enlargement of the spleen coincident with a blast crisis and leukocytosis of 500,000/cu mm. His condition was refractory to treatment with platelet transfusions, splenic radiation, and chemotherapy, and he died from intracranial bleeding.

Autopsy findings indicated leukemic infiltrates about many of the bronchi. Within the pulmonary parenchyma, focal necrosis was noted but no organisms were seen. Pleural fluid and pleural adhesions were noted on the right. Leukemic infiltrates were demonstrated in most organ systems.

Case 4.—A 7½-year-old boy was vomiting and had diarrhea and fever. Examination showed an undergrown, chronically ill-appearing boy with multiple cafe-au-lait spots over the trunk and axillae, bilateral papilledema, and severe splenomegaly. A xanthoma was noted on the left knee. Laboratory data on admission are given in Table 1. Bone marrow aspirate was hypercellular, with a myeloid-erythroid ratio of 10:1. Megakaryocytes were decreased in number. Bone marrow karyotype revealed 46,XY with no Philadelphia chromosome. In vitro marrow culture disclosed preponderantly monocytoid differentiation. Serum CSA was slightly increased. Family history was unknown (adopted). Limited investigations were allowed, and all therapy was refused by the foster parents. The CT and roentgenograms of the optic foramina and skull showed no abnormalities. The CSF contained normal amounts of protein and glucose and no cells. The patient was readmitted to the hospital in acute respiratory distress one month later, at which time he had right lower lobe collapse. He continued to suffer coughing paroxysms during a two-month period prior to his death, and he finally became blind and hemiparetic before his death. No autopsy was performed.

Case 5.—A 2½-year 1-month-old boy was noted at routine examination to have splenomegaly and leukocytosis. Examination showed a spleen palpable 7 cm below the left costal margin, liver 4 cm below right costal margin, and mild cervical adenopathy. Numerous maculopapular erythematous lesions were noted over the right thigh and anterior tibia. Biopsy specimen of a skin lesion showed perivascular foci of immature inflammatory cells without xanthomatous or neurofibromatous component. A juvenile xanthogranuloma had been excised from the scalp at 1 year of age. There was no family history of neurofibromatosis, xanthomata, or leukemia. Results of hematologic studies are given in Table 1. Bone marrow aspirate was hypercellular, with decreased megakaryocytes and increased myeloid/erythroid ratio. The bone marrow karyotype was normal, 46,XY, and no Philadelphia chromosome was identified. In vitro bone marrow culture disclosed spontaneous colony formation with preponderantly monocyte maturation. Serum CSA was greatly elevated.

The patient received no treatment for six months after initial visit. Gradual deterioration with increasing leukocytosis and progressive hepatosplenomegaly subsequently led to three courses of combination chemotherapy resulting in decreased WBC count and decreased splenomegaly. His course was characterized by recurrent hepatosplenomegaly, leukemic infiltrates of the abdominal and chest wall, and recurrent pulmonary symptoms. A liver-spleen scan showed persistent splenic hypofunction unchanged by chemotherapy or splenic irradiation. He died 14 months after diagnosis. Autopsy was not performed.

COMMENT

The majority of children with the myeloproliferative disorder called CGL can be classified into the juvenile or adult type.[2] Familial forms of the disease as well as occasional patients who defy classification may also be seen.[2] The disease is characterized by peripheral leukocytosis with increased numbers of granulocytic cells at all levels of maturation. Results of bone marrow examination are abnormal in that there is a relative and absolute increase in granulocytic cells at all levels of maturation without a preponderance of blast forms. Megakaryocytes are decreased in the juvenile form but present in normal numbers in the adult form. Monocytosis is frequently noted in juvenile CGL, and in vitro cell cultures produce preponderantly monocytic colonies.[6,17] Because of this observation, it is postulated that juvenile CGL is a form of acute monocytic leukemia.[5] The elaboration of CSA by a malignant monocyte may be responsible for the associated neutrophilia. The persistent CSA production in the presence of neutrophilia suggests a defect in feedback inhibition.[17]

Chronic granulocytic leukemia of either variety is rare in childhood. In a recent review of 649 cases of childhood leukemia at St Jude's Children's

Research Hospital, Memphis, Tenn, only 18 patients (2.8%) were found to have CGL and six of these were classified as having the juvenile form.[2] Weisgerber et al reported an experience of 25 cases of juvenile CGL during a 14-year period in France.[18] Eisenberg and Wallerstein found 30 cases in the literature prior to 1934 and Hardisty et al an additional 104 cases prior to 1964.[1,19] Approximately 50 additional cases can be found in the literature.[20-32]

Juvenile CGL is a disease seen primarily in male subjects. In a recent series of 12 well-studied cases, 11 were male.[33] Our five patients with juvenile CGL were all male. In the same time period, three other patients with the clinical picture of CGL were seen. One male patient had the adult form with the Philadelphia chromosome while two female patients (one with associated neurofibromatosis) were not classifiable into either the adult or juvenile form. No sex-linked pattern of inheritance has been noted.

Previous reports have stressed an eczematoid facial rash as part of the clinical picture in juvenile CGL.[1,34] Only one of our patients had an eczematoid rash. It was located on the trunk and was not clinically important. Two patients showed recurrent leukemic skin infiltrates that were varied in their appearance. Case 5 showed erythematous maculopapular lesions scattered over the legs while case 2 showed the curious circular areas of induration and erythema with central clearing. These lesions appeared frequently and did not appear to be related to chemotherapy. In none of our cases did a previously recognized leukemic infiltrate become xanthomatous, as has been suggested in a case of adult CGL.[35]

The most consistent skin lesions were xanthomata, which were noted in three of the five patients (Table 2). In two cases, the onset of xanthomata antedated the leukemia diagnosis by one year, and in one case, it was noted at the time of the leukemia diagnosis. Conditions previously associated with xanthomata in children include histiocytosis, familial hyperlipidemia, hypothyroidism, and the glycogenoses.[36] Xanthomata have been reported to precede and accompany leukemia in children and adults. Thelander in 1949 described an infant who (1) at 3 months of age was noted to have scalp xanthomata, (2) at 6 months had a diagnosis of myelogenous leukemia with massive hepatosplenomegaly, and (3) at 26 months died after intermittent respiratory insufficiency.[37] Denys and Malbrain[38] proposed the term "xantholeukemia" when reporting a similar case, noting two similar cases reported by Crocker.[39] Eleven similar cases of childhood myelogenous leukemia and xanthomata have been reported.[1,40-43]

Two of the five patients had multiple cafe-au-lait spots compatible with the diagnosis of neurofibromatosis, and both of these also had cutaneous xanthomata. An association between xanthoma and neurofibromatosis has been well documented.[44-46] Since xanthoma may be the earliest manifestation of neurofibromatosis, one could postulate that case 5 may have had underlying neurofibromatosis as well.[47]

Royer et al first noted the coincidence of neurofibromatosis and childhood leukemia.[48] Subsequent reports have emphasized the association between leukemia, neurofibromatosis, and cutaneous xanthomata, so that the interrelationship seems firmly established.[28-31,40,47-51] Of interest is the high incidence of nonlymphocytic leukemia in patients with neurofibromatosis when compared with that noted in a general pediatric population.[47] Of 29 cases of neurofibromatosis and leukemia reviewed by Bader and Miller,[47] 20 had nonlymphocytic leukemia, and eight of these were CGL. The addition to this group of our three cases (two juvenile CGL, one unclassified CGL) would give a total of 32 cases, of which 11 (34%) had the combination of neurofibromatosis and CGL. In view of the relative rarity of CGL in children, the preponderance of CGL noted in association with neurofibromatosis is striking. Also of interest is the rather low incidence of the adult form of CGL (Philadelphia chromosome present) in this group—two out of 11 cases when considering our patients and those reviewed by Bader and Miller.[47]

Previous studies have not reported chromosomal abnormalities in patients with combined CGL and neurofibromatosis other than the presence of the Philadelphia chromosome in patients with the adult form.[47] In our patients, chromosome analysis using Giemsa and quinacrine mustard banding techniques revealed no abnormalities other than the 46,XY,Y inversion noted in case 2. The presence of the same alternation in skin fibroblasts of this patient make it unlikely that it was associated with malignant hematopoietic cell lines.

Pulmonary symptoms were a continuing problem in our patients. These symptoms varied from chronic tachypnea and cough to episodes of bronchospasm with expiratory wheezing and emphysema. The latter picture was unchanged by administration of epinephrine hydrochloride (Adrenalin) or bronchodilators. No episodes of bacterial pneumonia were seen, and antibiotic therapy did not alter the clinical course. Although no antemortem lung biopsies were performed, postmortem specimens did not disclose evidence of viral or fungal disease. Roentgenographic studies repeatedly demonstrated shifting atelectasis. Cytoreductive chemotherapy seemed to relieve the pulmonary symptoms and was particularly effective for patients with a bronchospastic component. Autopsy confirmation of peribronchial cuffing by immature granulocytes would support a malignant rather than an infectious etiology for the respiratory symptoms. A direct association between respiratory distress and the blood leukocyte doubling rate has been shown in hyperleukocytic leukemias.[52] Documented infection was negligible in all patients despite frequent chemotherapy-induced neutropenia. Suppurative adenopathy, previously stressed as characteristic of juvenile CGL, was not seen although patient 2 did have an episode of staphylococcal pyoderma.[34]

The best form of therapy for juvenile CGL remains to be determined. The poor response to alkylating agents has been well publicized and was noted in the one patient in whom it was attempted.[34] Because of the proposal that juvenile CGL is a form

of acute monocytic leukemia, attempts have been made to treat juvenile CGL with therapeutic regimens used for acute nonlymphocytic leukemia.[53] Of our three patients treated with combination chemotherapy, all had clinical and cytologic response with minimal toxic effects. The response by patient 3 was short with a five-month survival, whereas patient 2 survived 18 months and patient 5 survived 14 months. The two patients who did not receive intensive chemotherapy survived 21 months and five months. It has been suggested that optimally timed administration of combination chemotherapy may improve the quality of life rather than survival time.[53] Our observation of these five patients tends to support this view.

This work was supported in part by grant MRIS 0754 from the Medical Research Service of the Veterans Administration; the Medical Research Foundation of Oregon, Inc, Portland; Public Health Service grant 1936001786B8; and grant 1 R10 CA26044-01 from the National Cancer Institute. Dr Bagby is a Research Associate of the Veterans Administration.

The following physicians made referrals: Robert A. Mendelson, James Nusrala, MD, Gordon Caron, MD, David Bell, MD, and Richard Steinberg, MD. Fetal hemoglobin studies were performed by Marilyn Jones, PhD, and the gamma chain analysis by Walter Shroeder, PhD. Bone marrow karyotypes were prepared by Douglas Hepburn in the laboratory of Ellen Magenis, MD. Autopsies were performed by Scott Miller, MD, and Peter Stenzel, MD.

Pneumococcal Empyema

Outcome of Medical Management

Dianne Murphy, MD; Charles H. Lockhart, MD; James K. Todd, MD

• Physicians vary considerably in their opinion as to the duration of hospitalization and degree of surgical intervention for children with pneumococcal empyema. The development of pneumatoceles and persistence of fever or loculated pleural fluid are causes of debate and concern. We reviewed the records of 21 children with confirmed pneumococcal pneumonia. Ten of the 12 with no pleural fluid became afebrile within 48 hours of appropriate antibiotic therapy, whereas the nine with empyema remained febrile an average of 7.1 days (minimum estimate) in spite of documented sterile cultures within 24 hours in five of the patients. Although chest tube and thoracentesis drainage could not remove all the pleural fluid, and pneumatoceles developed in five of the nine children, long-term follow-up studies including chest roentgenograms and pulmonary function testing demonstrated a gradual but complete recovery that did not require long-term hospitalization, continued parenteral antibiotic therapy, or invasive surgical procedures.

(*Am J Dis Child* 134:659-662, 1980)

Pneumococcal empyema is a disease that, by many reports,[1-5] has decreased in frequency of occurrence, perhaps due to a concomitant decrease in pneumonia caused by *Streptococcus pneumoniae*. Early outpatient antibiotic therapy may explain this apparent change in incidence; Siegel et al[6] have recently described ten patients with confirmed pneumococcal empyema of whom seven were culture-negative (etiology established by counterimmunoelectrophoresis [CIE]) due to the prior administration of antibiotics. The observation that these patients spent an average of 18 days in the hospital suggests that questions regarding management of empyema caused by *S pneumoniae* may go beyond the selection of appropriate antibiotic therapy. Prolonged fever, incomplete drainage of the pleural space, and development of pneumatoceles may all generate physician anxiety that could result in more vigorous surgical therapy or prolonged hospital observation.

The following is a report of nine cases of proved pneumococcal empyema with a high frequency of pneumatocele formation and prolonged fever despite effective antibacterial therapy. Long-term follow-up on eight of these children in the form of chest roentgenograms and pulmonary function studies in five provides evidence to support a patient, conservative approach to the management of pneumococcal empyema.

SUBJECTS AND METHODS

A retrospective chart review of all children discharged from the Children's Hospital of Denver with the diagnosis of pneumococcal empyema or pneumonia for the years 1971 through 1977 was undertaken. Sixty-two of 77 charts were available. 24 of these were selected for review because of documentation of etiology by positive blood, pleural fluid, or tracheal aspirate cultures. Antibiotic susceptibility testing was not routinely performed on these isolates.

Pulmonary function tests were administered in respiratory therapy and anesthesiology departments. Measurements included forced expiratory volume, forced vital capacity, expiratory reserve volume, functional residual capacity, residual volume, total lung capacity, single-breath nitrogen washout, and flow-volume loop.

Initial and follow-up chest roentgenograms of all children with pleural fluid were reviewed by a pediatric radiologist.

RESULTS

Of the 62 patients reviewed, 23 had confirmed *S pneumoniae* pneumonia by pleural fluid, blood, or tracheal aspirate culture. One additional patient, who had received previous antibiotic therapy, had the diagnosis confirmed by CIE of pleural fluid. Tracheal aspirates were performed under direct visualization of the larynx in patients with febrile lobar pneumonia. A predominant growth of *S pneumoniae* associated with neutrophils on Gram's stain was considered presumptive evidence of pneumococcal pneumonia. Three of the 24 had the diagnosis established at autopsy; they are excluded in the following discussion as all died of causes apparently unrelated to their pneumonia. Nine of the remaining 21 children had substantial pleural fluid radiologically and were categorized as having pneumococcal empyema because of positive pleural or blood cultures. The remaining 12 children had proved (eight by blood, four by tracheal aspirate) pneumococcal pneumonia, but no evidence of effusion.

The average age of the 12 patients with pneumonia without empyema was 3.3 years, with a range of 5 weeks to 14 years. There were four infants in this group. These children had localized involvement on chest roentgenograms, confined to one or more lobes. None had pneumatoceles. Ten of these children with pneumonia were afebrile within an average of 21 hours

after initiating appropriate antibiotic therapy. The only two children with pneumonia who were still febrile after 48 hours had underlying disease processes that were believed to contribute to the fever. Radiologically, the degree of lung involvement was much less in this group compared with those with empyema.

The characteristics of the nine children with pneumonia and empyema are summarized in Table 1. The average age was 7.3 years, with a range from 3 to 14 years. There were no infants in this group as compared with the four in the pneumonia without empyema group. All diagnostic cultures were from blood (two) or pleural fluid (six). One of the pleural fluid specimens was negative on culture but positive on CIE. This child had received antimicrobial therapy prior to admission. All of the empyema patients were in a much improved clinical condition (decreased toxicity and respiratory distress) within 24 to 48 hours of appropriate antibiotic therapy, despite persistent high fevers (temperature greater than 38 °C). Repeated pleural fluid or blood cultures were sterile within 24 to 48 hours after the institution of antibiotic therapy in five patients. From time of admission, the average number of days of fever (minimum estimate) was 7.4 days, with a range of two to greater than ten days. Four children were still febrile at the time of discharge from the hospital.

The chest radiologic findings of the empyema patients were extensive on admission, with either total hemithorax or multilobe involvement in five of the nine patients. Extensive pleural fluid accumulations were present in seven of the nine children. Two children had extensive lower lobe involvement with only moderate to minimal pleural fluid. These two patients experienced the shortest febrile period. Five patients' roentgenograms showed evidence of pneumatocele formation during therapy.

Extensive radiologic improvement was usually not apparent for one to two weeks after the initiation of therapy, and pleural thickening was often present for months thereafter.

Patient 1 (Fig 1) demonstrated a large pneumatocele with air fluid levels within the first week of therapy. At that point in therapy, the patient's condition was clinically much improved with sterile chest tube drainage. Therefore, despite the possibility of abscess formation and the continued fever, we elected to treat him conservatively. His chest tube was removed at 48 hours and he continued to improve with oral therapy, with

resolution of his apparent intrapulmonary loculation.

Patient 2 (Fig 2) had been hospitalized for four days at another hospital before being transferred to our hospital. On admission, his chest roentgenogram demonstrated multiple pneumatoceles that became more prominent while he was given parenteral therapy. The pleural fluid was culture-negative but CIE-positive for *S pneumoniae*. The patient was in no respiratory distress and clinically doing well at discharge after five days of parenteral therapy, in spite of the failure of chest tubes to adequately drain the loculated pleural effusion. Again, repeated chest roentgenograms demonstrated progressive resolution of fluids, infiltrates, and pneumatoceles.

Only four children were treated with chest tube drainage, the longest for four days. Three children were treated with thoracentesis alone. All had persistent infiltrates and pleural fluid in spite of attempts at drainage, and four had pneumatoceles present at the time of discharge. Follow-up roentgenograms in eight children one month to seven years after discharge demonstrated normal findings in six and minimal residual parenchymal or pleural disease in two.

Table 2 lists the results of pulmonary function tests performed on the five patients available for follow-up investigation. The expected normal values are indicated, as well as the time from discharge to the time of the study. All the children, except patient 2, had some increase in their residual volume. There was, however, no evidence of obstructive airway disease or compromised function by forced expiratory volume studies, single-breath nitrogen washout, or flow-volume loop. All of the children were well, participating in normal activities and with no exercise limitations. None had an increased frequency of school absenteeism (averaging two to three days per school year), illnesses, or pulmonary disease, and none had scoliosis.

COMMENT

Our data suggest that children with severe pneumococcal empyema may be treated with appropriate antibiotics and conservative drainage procedures with good outcome, assuming the causative organism is demon-

strated to be a susceptible *S pneumoniae*. Recent reports of pneumococci resistant to penicillin necessitate a thorough evaluation of all such organisms associated with serious clinical infection.[7] Early chest tube drainage or thoracentesis may relieve respiratory symptoms caused by excessive empyema volume and may reduce the duration of fever, which tends to be prolonged in the presence of persistent fluid. However, these procedures *rarely* eliminate all of the fluid and may be terminated once the child's condition is clinically improved despite prolonged fever, persistent pleural fluid, or the development of pneumatoceles. After resolution of respiratory distress and once oral antibiotics and fluids are tolerated, the patient may be discharged with close follow-up. Subsequent pulmonary function studies and chest roentgenograms have demonstrated no serious abnormalities when this approach is adopted.

Physicians may become concerned when the patient with pneumococcal empyema does not rapidly become afebrile. In an older review of pneumococcal pneumonia (as in the present study), the rapidity of defervescence with appropriate antibiotic therapy was notable.[8] Some authors[9] did state that a prolonged convalescence with persistent empyema could be accompanied by low-grade temperature elevation. In 1944, Tillett et al[8] stated that fever in the patient with pneumococcal empyema is not a reason to change approach or therapy if the patient is demonstrating clinical improvement.

Patients with pneumatoceles have prompted some authors to treat pneumococcal empyema as they do staphylococcal empyema.[10] Very aggressive therapy such as rib resection, open drainage, and decortication was previously recommended for staphylococcal empyema.[1,11,12] However, more recently, other authors have taken a different approach,[5,13,14] stating that not only are there better antistaphylococcal antibiotics available, but the child's ability to resolve a thickened pleura is vastly superior to that of the adult. They point out that if the child's condition is improving clinically, one can wait for weeks or months for the roentgenogram to clear.

Pneumatoceles have not contributed to the morbidity of pneumonia, as noted by Hendren and Haggerty,[15] Ravitch and Fein,[4] and most recently in 1978 by Sullivan et al[16] and Asmar et al.[17]

All nine of the children in the present series were in clinically improved conditions without respiratory distress after 24 to 48 hours of appropriate antibiotic therapy, despite persistent fever and sometimes apparently worsening chest roentgenograms. These patients progressed to complete healing without extensive surgical drainage or prolonged hospitalization. On long-term follow-up, none was left with decreased pulmonary function, impaired thorax growth, or scoliosis. The only serious abnormality in pulmonary function testing was the increased residual volume. This measurement is highly variable and when increased is usually associated with obstructive airway disease. We have no evidence of obstructive disease from the normal forced expiratory volume, single-breath nitrogen washouts, or flow-volume loop studies. In 1966, Groff et al[3] followed up 21 cases of empyema in children caused by a variety of organisms; they found all the children to be asymptomatic with no scoliosis or decrease in exercise tolerance. Although two of the 21 patients received rib resections, the authors stated, "It is our strong feeling that adequate chest tube drainage in children can be obtained without rib resection. It is rare that closed tube drainage needs to be converted to open drainage tube." Pagtakhan and Chernick,[14] in their chapter on the therapy of empyema in children, support this view and state that if the symptoms are relieved after closed drainage the tube can often be removed after 24 hours. Wise et al[18] reviewed 15 patients with staphylococcal pneumonia and empyema treated conservatively. They found that these patients had no increase in illness, no decrease in growth as compared with siblings, and that all their pulmonary functions were normal.

We believe our data support the same conclusion for the treatment of pneumococcal empyema, assuming appropriate antibiotic therapy is selected. The nine children described here responded favorably to conservative therapy despite extensive chest disease, incomplete drainage of pleural fluid, pneumatoceles, and prolonged fever.

John B. Campbell, MD, evaluated the chest roentgenograms. Lynda Gregory helped prepare the manuscript.

Behavioral Symptom Substitution in Children Cured of Encopresis

Melvin D. Levine, MD; Peter Mazonson; Harry Bakow, PhD

• **Follow-up data were obtained on 47 children who had been treated for encopresis with an initial catharsis, maintenance laxative therapy, demystification, symptom-related counseling, and close follow-up. Behavioral inventories were used at the beginning of treatment and three years later to determine whether any significant symptom substitution occurred in children cured of encopresis. Little evidence of this was uncovered. There was a comparison of cured and uncured children with respect to behavioral profiles at the start of treatment and three years later. The uncured group showed more aggressive behaviors initially, and also were more socially withdrawn at the start of treatment, although this was not evident three years later. Monitoring of associated behaviors should be an important part of the management of encopresis.**

(*Am J Dis Child* 134:663-667, 1980)

Encopresis is a common childhood plight, the optimal management of which is a subject of continuing debate.[1-5] The outcome of treatment is likely to reflect itself not only in bowel function, but also in a child's overall behavior and life adjustment. Therefore, the results of intervention may be seen not merely in the attainment of continence, but also in a wide range of associated behavioral outcomes. The present study was undertaken to determine if children cured of encopresis through a pediatric regimen replaced their bowel symptoms with other maladaptive behaviors following their "cure."

BACKGROUND

Psychodynamically oriented interpretations of encopresis commonly refer to a child's "need" to be incontinent, implying that the symptom has some utility in the context of disturbed families and problem children. From a therapeutic perspective, it might follow that treatment of family psychopathologic problems must take precedence.[6-8] One might anticipate that merely removing the symptom of encopresis would engender deterioration, or, at least, significant substitution of other maladaptive behaviors. If this were true, one could hypothesize that pediatrically managed children would be in danger of decompensating in other psychological areas following symptomatic relief of their bowel dysfunction.

A previous report described the evaluation of a pediatric treatment program for patients with encopresis at the Children's Hospital Medical Center in Boston.[2] After an initial case analysis using interviews and special questionnaires, the following therapeutic program was implemented: (1) an initial "demystification" or explanation to parents and the child about the cause and apparent pathophysiologic condition culminating in the problem; (2) an explicit effort to alleviate guilt and communicate in a nonaccusatory mode; (3) an initial catharsis during which the child was disimpacted completely with enemas and laxatives. The effectiveness of this procedure was documented by plain x-ray films of the abdomen taken before and after the procedure[9]; (4) maintenance laxative, and/or stool softener therapy for at least six months; (5) a bowel retraining program consisting of twice a day use of the bathroom for ten minutes each time (at the same times each day) reinforced with rewards for children under 8; (6) regular follow-up and monitoring, including availability for phone checks and scheduled return visits to discuss progress, to build rapport, and to deal with concerns related to the bowel problem.

The management program did not

Table 1.—Items On School-Age Behavioral Inventory

Social Withdrawal Behaviors	
Is a "loner"	Prefers adults as friends
Has no "real friends"	Gets picked on
Loses friends easily	Gets jealous easily
Has mostly younger friends	Is slow to make friends
Has mostly older friends	Likes to act like opposite sex
Has mostly friends of opposite sex	Likes to wear clothes of opposite sex
Has no best friend	Constantly fights with brothers/sisters
	Often watches TV alone in afternoon
Antisocial-Aggressive Behaviors	
Tells lies	Destroys objects at home
Steals at home	Destroys objects away from home
Steals away from home	Disobeys adults
Often plays with matches	Acts fearless
Smokes cigarettes	Cheats in games
Uses foul language	Skips school
Bullies other children	Gets in trouble with neighbors
	Cruel to animals
Affective-Dependent Behaviors	
Is moody	Is often sad
Has a bad temper	Tries to sleep with parents
Cries easily	Is often very quiet
Is a worrier	Whines often
Has bad dreams	Has many fears
	Is often tired
Somatic Manifestations	
Too concerned about cleanliness	Sucks thumb
Stutters or stammers	Has nervous twitches
Wets bed or pants often	Complains of feeling ill often
Often has headaches	Has constipation
Soils underwear	Is too neat and orderly
Overeats often	Bites nails

include referral for psychotherapy, surgical evaluation, a barium enema, or a rectal biopsy. Follow-up visits (lasting 30 minutes or less) occurred every four to six weeks during the first six months, and less often after that. They did not include discussions of family problems or other psychodynamic issues apart from those directly related to management of the child's encopresis. Most of the time was spent discussing the problem alone with the child. The parents were invited in toward the end of the session to review medications and to ask questions.

As reported in a previous study, approximately 70% of children achieved a cure within one year of the start of treatment. This was defined as six months without incontinence. Another 25% showed substantial improvement, but still had occasional "accidents." Five percent were noted to be treatment-resistant at the end of a one-year period.[2]

METHODS

The present study concentrated primarily on those youngsters whose fecal incontinence subsided after undergoing pediatric treatment. As part of an initial evaluation, parents were asked to fill out a 53-item school-age behavioral symptom inventory (Table 1). This was part of a comprehensive parent questionnaire for children with encopresis (copies of this questionnaire and its instruction manual are available on request). For this study, the parents completed the same inventory at one and three years after the initiation of treatment. This enabled the investigators to track longitudinally a wide array of behavioral themes.

The behavioral symptom inventory is divided into four categories: social withdrawal behaviors; antisocial-aggressive behaviors; affective-dependent behaviors; and somatic manifestations. Within each category there are 11 to 15 items. Parents are asked to indicate whether an item "definitely applies," "applies somewhat," or "does not apply." They can also check the category "cannot say." Each item is rated with a 0 for "definitely applies," a 1 for "applies somewhat," and a 2 for "does not apply." For each category of behavior, a total score is obtained and divided by the number of items answered. This excludes items in the "cannot say" column. If more than three "cannot say" items were checked, the category is considered unscorable for that child. For each category of behavior a mean score is obtained that ranges from 0 to 2, with higher numbers indicating "better behavior."

In order to standardize the behavioral symptom inventory for this and other studies, a comparison group of 98 children with no known major academic problems was selected from a socioeconomically heterogenous school system in the greater Boston area. The children were of comparable mean age and socioeconomic status, although the comparison group contained a higher proportion of girls (40% vs 21%). Parents were asked to fill out the behavioral inventory for these youngsters. Compliance was greater than 90%. In addition to overall standardization of the inventories, there was scrutiny of the ways in which variations in scores related to sex and age. Statistically significant sex differences were not demonstrable in any behavioral category. Changes with age are reflected in Fig 1. These behavioral inventories are currently under processes of validation on normative samples and in various behavioral and learning problem clinics.

To study behavioral change in children treated for encopresis, questionnaires were mailed three years after the initial visit. Parents were asked to complete the behavioral inventory and to answer questions about the child's current bowel function and academic performance. Approximately 70% returned the forms. This included 36 children who had been cured of encopresis and 11 who had not. Mean behavioral scores were computed for the same group of children at the initial visit and the three-year checkpoint.

RESULTS

Scores for the behavioral categories were calculated. Figure 1, top left, shows a comparison of social withdrawal behaviors. The solid line at the top reflects the mean comparison group scores at each age. Although the comparison group were roughly evenly distributed by sex, the encopresis groups were predominantly male. Because comparison group data showed no statistically significant sex differences, sexes were combined for this analysis.

Beginning at age 7, there was a major difference in social withdrawal behaviors between the comparison group and the children before treatment. There were no significant differences at the ages of 5 and 6. With age it is clear and not surprising that social withdrawal tended to increase

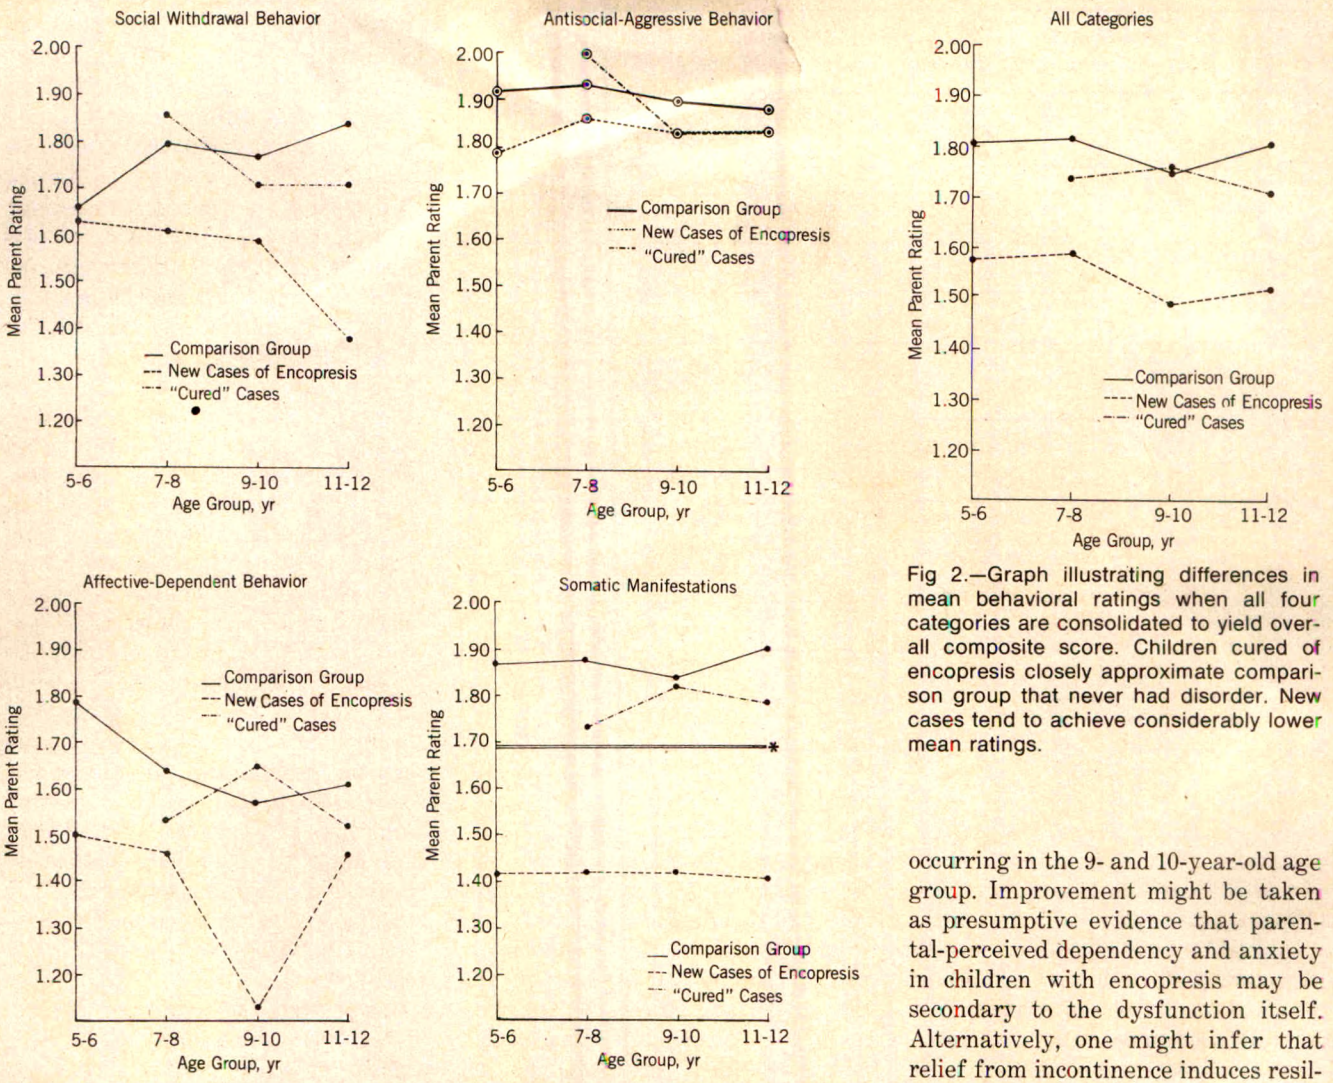

Fig 1.—Four graphs illustrate mean behavioral scores in each of four categories at specific age levels. In each, comparison group without encopresis is contrasted to children at start of treatment program and to those same youngsters three years later. Significant differences emerge, suggesting behavioral improvement after symptom relief. Mean rating based on constipation and soiling items without other somatic symptoms (asterisk).

Fig 2.—Graph illustrating differences in mean behavioral ratings when all four categories are consolidated to yield overall composite score. Children cured of encopresis closely approximate comparison group that never had disorder. New cases tend to achieve considerably lower mean ratings.

in children with encopresis. Peer and adult ridicule and rejection over time may have fostered this process. The middle line in Fig 1, top left, traces a statistically significant improvement in social integration among youngsters cured of encopresis. There was a trend away from isolation toward more engagement in peer and family interaction.

Figure 1, top right, is a comparison of antisocial-aggressive behaviors. Here it can be seen that antisocial-aggressive traits were not characteristic of new encopretic children at any age. Consequently, one discerns little alteration in these scores before and after treatment.

The affective-dependent behavior patterns are shown in Fig 1, bottom left, where some of the most dramatic differences are seen. These behaviors are thought to reflect signs of depression, affective lability, and anxiety. At all ages, there were significant differences between the pretreatment and the comparison group. Following the conquest of encopresis, patients approximated the comparison group. One can see particularly large changes occurring in the 9- and 10-year-old age group. Improvement might be taken as presumptive evidence that parental-perceived dependency and anxiety in children with encopresis may be secondary to the dysfunction itself. Alternatively, one might infer that relief from incontinence induces resiliency in affective areas and personality development. At any rate, it would appear that the cure of encopresis exerted its major behavioral effects on the alleviation of chronic anxiety, dependency, and incipient depression.

Figure 1, bottom right, traces somatic manifestations. Since several of the items on the inventory relate directly to symptoms such as constipation and soiling, these in themselves would lower scores in this area. In Fig 1, bottom right, the double line with an asterisk represents the level one would see in a child with encopresis who had only abdominal symptoms. Untreated cases of encopresis scored on the average well below the threshold, indicating that affected youngsters tended also to have extraabdominal somatic symptoms. There was considerable resiliency in the group

Table 2.—Mean Behavioral Rating Scores: Comparison of Ultimately Cured and Uncured Groups, at Start of Treatment

Category	Comparison Group Mean (SD)	Cured Group (N = 31) Mean (SD)	Uncured Group (N = 11) Mean (SD)
Social withdrawal	1.79 (0.26)	1.60 (0.24)	1.44 (0.29)
Antisocial-aggressive	1.91 (0.14)	1.82 (0.11)	1.46 (0.13)
Affective-dependent	1.39 (0.31)	1.39 (0.27)	1.40 (0.24)
Somatic manifestations	1.87 (0.13)	1.41 (0.18)	1.46 (0.19)

Table 3.—Mean Behavioral Rating Scores: Comparison of Cured and Uncured Groups After Three Years

Category	Comparison Group Mean (SD)	Cured Group (N = 36) Mean (SD)	Uncured Group (N = 11) Mean (SD)
Social withdrawal	1.79 (0.26)	1.71 (0.29)	1.83 (0.33)
Antisocial-aggressive	1.91 (0.14)	1.84 (0.17)	1.64 (0.26)
Affective-dependent	1.39 (0.31)	1.61 (0.21)	1.36 (0.24)
Somatic manifestations	1.87 (0.13)	1.76 (0.24)	1.47 (0.19)

cured of encopresis, with no evidence of generalized substitution of new physical symptoms.

In Fig 2, all categories of behavior were collapsed into one composite score and a behavioral mean obtained for each age group. This illustrates again that untreated children with encopresis had the lowest scores, while cured children closely approximated the comparison group, especially at ages 9 and 10.

An effort was made to characterize behavioral symptom patterns in the 11 children who were *not* cured. Table 2 compares mean behavioral scores at the start of treatment for those who were ultimately cured and for those who were treatment-resistant after three years. Statistically significant differences were evident in social withdrawal tendencies and antisocial-aggressive behaviors. Such propensities toward social maladaptation might be considered flags of poor prognosis. There were no significant differences in affective-dependent behaviors or in somatic manifestations.

Comparison between cured and uncured patients at the three-year checkpoint are seen in Table 3. Surprisingly, the uncured group made substantial gains in social adaptation. It may be that the alleviation of guilt, the process of demystification, and the supportive aspects of management were therapeutic even though bowel symptom treatment had not succeeded. The uncured children tended to score better in these areas than did untreated patients at the same ages. The latter showed little change in affective-dependent behaviors and somatic manifestations.

The major group differences in somatic manifestations reflected largely relief of the encopresis-related symptoms. The cured group showed considerable improvement in affective-dependent traits, while the uncured did not shed the signs of anxiety, depression, and excessive dependence. From these data, there is no way to determine whether the persistence of affective-dependent behaviors in the uncured group was a reason for their treatment resistance or the result of continuing poorly controlled incontinence.

As part of the initial and follow-up evaluation of children in this study, parents were asked to rate school performance. For purposes of this report, three areas will be described: reading, spelling, and arithmetic. Each child's academic attainment was rated on a scale from 0 to 3, with 0 representing failure and 3 advanced achievement. A total score was obtained for performance in all three areas before and after treatment, ranging from 0 to 9. The mean academic score for children cured of encopresis was 6.10 at the start of treatment, and 5.71 at the three-year follow-up assessment, indicating a statistically insignificant decline in perceived academic performance. The initial academic ratings of uncured children was substantially lower, 5.10. However, after three years, the uncured children showed a slight improvement in academic performance (to a rating of 5.50). To evaluate this further, an individual case analysis was undertaken. Four youngsters from the cure group actually experienced a decline of two or more points in perceived reading achievement; 32 showed no significant changes with only minor fluctuations in academic performance. Of the 11 in the uncured group, none showed deterioration, while two showed significant improvement.

In general, the treatment of encopresis was associated with little impact on school performance. However, it should be emphasized that these scores represented parent perceptions rather than direct teacher ratings or standardized test results. Moreover, there were no available normative data on the age fluctuations of parent-perceived school performance in nonencopretic children.

Although there was overall parent-perceived improvement in behavior among youngsters who had been cured of encopresis, an effort was made to determine if any of the children suffered major behavioral deterioration following cure. To determine this, individual case analyses were performed. Eight of the 36 cured children were noted to have substituted one or more entirely new symptoms during treatment. In two of these, the new symptom was nail-biting. In two others, the only new trait was a tendency to be slow to make friends.

Another child was said to undergo prolonged periods of sadness, but this youngster had endured the death of his father. Thus, there was no consistent trend toward acquisition of any specific symptom or cluster in the cured group. In no case did a child's condition deteriorate to the point where he or she was hospitalized for emotional difficulties, arrested by the police, suspended from school, or said to have developed highly troublesome new symptoms such as fire-setting, school phobia, or stealing. There were no intercurrent divorces or marital separations in the cure group.

COMMENT

It is clear from this study that encopresis is seldom an isolated symptom. Bowel incontinence commonly is clustered with other somatic symptoms, with social withdrawal, with affective changes, and with increasing dependency. The high prevalence of associated behavioral symptoms may either be secondary to despair over poor bowel control or the product of the same forces that lead to encopresis. Regardless of their sources, it is clear that such behaviors need to be monitored as an integral part of treatment outcome.

This study offers evidence that the pediatric cure of encopresis is unlikely to result in a major deterioration of behavior. In fact, relief of incontinence was associated with a generalized improvement in the traits surveyed.

There is a need to interpret these findings with some caution: The children studied were likely to have had more severe symptoms of encopresis than those encountered in a primary care setting; many of them had been managed unsuccessfully in the community, and were referred to the medical center for specialized evaluation and higher intensity intervention.[10] Furthermore, since these youngsters were referred to a pediatric rather than a child psychiatric clinic, one might question whether they had less associated psychopathologic problems than children undergoing psychotherapy or psychiatric evaluation for encopresis. It would be important to study differences between encopretic children in pediatric care and those in psychiatric settings. It would be useful to compare those receiving pediatric treatment for encopresis to youngsters receiving psychotherapy and to children receiving pediatric treatment for other chronic disorders of development or function.

In this study, there may have been "halo effects" introduced by parents who were euphoric over improved household odors and an end to soiled underpants buried in the garden! Future behavioral outcome studies need to examine the child directly, measuring such factors as self-esteem and affect. Despite the limitations of reported data, behavioral inventories can be helpful to pediatricians in observing the range of secondary effects of childhood functional disorders, in assessing mental health, and in evaluating the broad functional outcomes of any intervention. The utilization of such tools can be useful, both from an investigational and clinical standpoint. Information so collected can be relevant in mapping management strategies, in assessing the likelihood of compliance, in determining the need for other interventions, and, to some extent, in predicting outcome.

We believe that this study further justifies a focused, supportive, and tenacious pediatric role in the management of the symptoms of encopresis. It tends to refute the notion that an exclusively pediatric effort concentrated on a functional problem for which help was sought is likely to result in deterioration in other areas of behavior. Psychotherapy or a family dynamics orientation certainly has a place in select cases in conjunction with pediatric treatment. In general, however, comprehensive pediatric management and directive counseling can have beneficial effects in helping children recover from incontinence and from its galaxy of associated maladaptive behaviors.

Tom Ferb, PhD, assisted in the statistical analyses, and Linda Evans helped prepare the manuscript.

Bacteremias due to *Haemophilus influenzae* and *Streptococcus pneumoniae*

Their Occurrence and Course in Children With Cancer

George R. Siber, MD

• **Nine *Haemophilus influenzae* and 24 *Streptococcus pneumoniae* bacteremias occurring in children with cancer during the years 1968 to 1977 were reviewed. The number of bacteremias due to these organisms remained relatively constant, in contrast with a sharp decrease in bacteremias caused by other organisms during this period. The highest incidence of bacteremia occurred in patients with acute leukemias and the lowest incidence in patients with solid tumors. Twenty-seven of 33 episodes occurred while patients were receiving chemotherapy. Nine bacteremias were fatal, but concurrent or superinfections contributed to death in six of these. Children with cancer who are receiving chemotherapy seem to be at higher risk of bacteremia and meningitis due to *H influenzae* and *Strep pneumoniae* than are normal children. New approaches to the prevention of these infections, such as the use of bacterial polysaccharide vaccines, deserve investigation.**

Patients with cancer frequently suffer serious infections, most often due to enteric Gram-negative bacteria and *Staphylococcus aureus*.[1] A review of positive blood cultures from pediatric cancer patients at the Children's Hospital Medical Center during the past ten years disclosed a sharp decrease in the incidence of all bacteremias, but a relatively constant number of bacteremias caused by the encapsulated pyogens *Haemophilus influenzae* and *Streptococcus pneumoniae*. These two organisms now account for a substantial proportion of the positive blood cultures in these patients. I have, therefore, reviewed the clinical features of bacteremias caused by these organisms and calculated disease-specific incidence rates with a view to identifying high-risk patients who are likely to benefit from immunization with pneumococcal and *H influenzae* type b polysaccharide vaccines.

MATERIALS AND METHODS

Bacteremias were ascertained by reviewing records of positive blood cultures in the clinical bacteriology laboratory of Children's Hospital Medical Center, Boston. The following criteria were adopted to distinguish bacteremias from contamination: blood cultures yielding *Staph aureus*, β-hemolytic streptococci, *Strep pneumoniae*, *H influenzae*, *Neisseria meningitidis*, Enterobacteriaceae, *Pseudomonas aeruginosa*, and other nonfermenting, Gram-negative rods were assumed to represent bacteremia; blood cultures yielding *Staph epidermidis*, α-hemolytic streptococci, bacillus species, and diphtheroids were considered to be contaminants when present in a single blood culture, and indicative of bacteremia when present in two or more blood cultures.

Blood cultures were inoculated into trypticase soy broth and thioglycollate broth from 1968 to 1973, into dextrose phosphate broth and thioglycollate broth from 1973 to 1975, and into *Brucella* broth and Columbia broth from 1975 to 1977. Prior to 1973, blood cultures were not routinely subcultured, but Gram stained before discarding the bottles after five to seven days. From 1973 to 1977, subcultures were performed onto chocolate agar after 24 hours and after seven days. Bacterial isolates were identified using standard bacteriologic techniques. *Haemophilus influenzae* was serotyped by agglutination with type-specific antisera obtained from Burroughs-Wellcome Laboratories, Research Triangle Park, NC, and *Strep pneumoniae* was serotyped at the Massachusetts State Laboratory, Boston, using the Quellung reaction with typing sera provided by the Center for Disease Control, Atlanta.

Census figures according to underlying illness were obtained from the computer records of the Sidney Farber Cancer Institute, Boston. The number of patient-years was calculated using the assumption that patients who were diagnosed or who died in a given year were observed for six months during that year, as follows: number of patient-years equals the number of survivors from previous years plus the number of deaths divided by two plus the number of new diagnoses divided by two. The total number of patients seen was calculated by adding the number of patients followed up in January 1968 to the number of patients diagnosed in each subsequent year. Children seen only in consultation or unavailable for follow-up were excluded from the calculations.

RESULTS

The number of bacteremias due to all organisms and due to *H influenzae* and *Strep pneumoniae* during each year from 1968 to 1977 is given in Table 1. The total number of bacteremias had decreased approximately threefold, whereas the number of bacteremias caused by *Strep pneumoniae* has remained relatively constant. Bacteremias due to *H influenzae* were observed only in the second five years of the survey. This may have resulted from the fact that routine subcultures onto chocolate agar were not performed prior to 1973. As a consequence, *H influenzae* bacteremias may have been missed because this organism typically produces little visible change in blood culture bottles.

Table 1.—Number of Bacteremias Seen Each Year due to *Haemophilus influenzae* and *Streptococcus pneumoniae*

	No. of Bacteremias by Etiology		
Year	All Organisms	*H influenzae*	*Strep pneumoniae*
1968	73	. . .	2
1969	75	. . .	4
1970	74	. . .	2
1971	53	. . .	3
1972	37	. . .	2
1973	39	2	2
1974	38	4	3
1975	16	2	2
1976	25	1	2
1977	22	0	2
Total	**452**	**9**	**24**

The rate of accrual of new patients during the study period was relatively constant, averaging 47 patients/year for acute lymphocytic leukemia, 9.2/year for acute myelocytic leukemia, 12/year for Hodgkin's disease, and 73/year for solid tumors. However, the number of deaths decreased dramatically, from 106/year during the first three years of the study to 54/year during the last three years. The decline in the number of deaths, which was especially prominent in patients with acute lymphocytic leukemia, reflects improved treatment rather than a declining patient population. The increased survival resulted in an increasing number of patient-years observed each year during the ten-year period, but an increasing proportion of these patient-years is comprised of long-term survivors who are no longer receiving therapy.

Table 2 gives the incidence rates of bacteremia, expressed as the number per 100,000 patients per year, according to underlying malignancy. The incidence rates for *H influenzae* bacteremia were based only on the number of patient-years observed during the last five years of the survey because the bacteriologic methods were not adequate to ascertain all cases prior to 1973. Although the number of pneumococcal bacteremias per year remained relatively constant (Table 1), the incidence decreased from 956/100,000 patient-years for the period 1968-1972 to 388/100,000 patient-years for the period 1973-1977. This decreased incidence may reflect the fact that an increasing number of patients were not receiving chemotherapy and therefore were at low risk.

Table 3 gives the epidemiologic features of bacteremias due to *H influenzae* and *Strep pneumoniae*. A child with neuroblastoma had three episodes of *H influenzae* type b bacteremia. The first episode, occurring at the time of diagnosis when the child was 15 months old, was associated with otitis media. The patient's condition responded promptly to treatment with intravenous chloramphenicol sodium succinate followed by ampicillin sodium. Four weeks later, while the patient was receiving oral ampicillin and was myelosuppressed from her first course of chemotherapy, pneumonia and bacteremia developed due to *H influenzae* type b resistant to ampicillin. This illness responded promptly to treatment with chloramphenicol. Thirteen months later, meningitis and pneumonia developed due

to *H influenzae* type b sensitive to ampicillin.

As expected, the age of patients with *H influenzae* bacteremia was lower than that of patients with pneumococcal bacteremia. However, only one patient was younger than 2 years and three patients were older than 5 years (9, 9, and 18 years).

Twenty-seven of 33 bacteremias occurred in patients receiving active therapy, four prior to therapy and two after completion of therapy. Patients with pneumococcal bacteremias were more often in relapse and profoundly granulocytopenic.

†Numbers in parentheses indicate the number of positive cultures from that site.

‡Rhinitis, oral mucositis, abdominal pain, and diarrhea were not considered foci for bacteremia. One patient with pneumococcal bacteremia had a dental abscess. Pharyngitis was never the sole focus of bacteremia.

§Rectal abscess, two patients; polymicrobial bacteremia, two; disseminated candidiasis and aspergillosis, two.

The clinical features of the bacteremias are given in Table 4. Pneumococcal bacteremias were associated with higher and more prolonged fever. The sites of infection were frequently minor or occult. Only one of nine episodes of *H influenzae* and four of 24 episodes of pneumococcal bacteremia were associated with meningitis. Most of the mortality associated with these infections was related to concurrent infections or superinfections with other organisms. In only three patients did death result primarily from infection by *H influenzae* or pneumococcus. Two of these patients had undergone splenectomy for staging of Hodgkin's disease: the first was an 18-year-old man in whom pneumocystis pneumonia developed one month after completing chemotherapy and total nodal irradiation for stage IIIB Hodgkin's disease. After his condition responded to a 12-day course of pentamidine isothiocyanate, rapidly progressive pneumonia and bacteremia developed due to *H influenzae* type b, and he died within 24 hours. The second patient was a 23-year-old woman in whom acute myelocytic leukemia developed three years after completing total nodal irradiation and chemotherapy for Hodgkin's disease. During initial therapy, pneumonia and bacteremia developed due to pneumococcus type 8 and she died within 24 hours with disseminated intravascular coagulation. A third patient with acute lymphocytic leukemia died of a cardiorespiratory arrest shortly after an intrathecal penicillin injection on the fourth day of treatment for pneumococcal meningitis.

COMMENT

During the ten years surveyed, the number of bacteremias in our pediatric cancer patients has declined markedly. Several factors may have contributed to this decrease. Therapeutic advances in the chemotherapy of acute lymphocytic leukemia, partic-

ularly the introduction of combination chemotherapy in 1972, resulted in decreased drug toxicity, fewer relapses, and enhanced survival. The prompt institution of empiric, broad-spectrum antibiotic therapy in cancer patients who were febrile and granulocytopenic may also have prevented bacteremias or prevented their recognition.

Despite the decrease in all bacteremias, the number caused by *H influenzae* and pneumococcus has remained relatively constant. As a consequence, the proportion of bacteremias caused by these organisms has increased from 3.6% during the first three years to 14.3% during the last three years of this review. Proportions of bacteremias due to these organisms, ranging from 6% to 12%, have also recently been reported from other pediatric oncology units.[2-4]

The disease-specific incidence rates were highest in patients with acute leukemias and lowest in those with solid tumors (Table 2). Only two episodes occurred in patients who had undergone splenectomy for Hodgkin's disease; however, both were rapidly fatal. Several factors should be kept in mind when interpreting the bacteremia rates in Table 2. The true incidence may have been underestimated because episodes of infection diagnosed and treated at other hospitals could not be ascertained. Furthermore, the rates were calculated using patients followed up both during and after cancer therapy. Since only two bacteremias occurred after patients had completed treatment, incidence figures during active therapy would be even higher than indicated, especially for solid tumors. On the other hand, the assiduous investigation of febrile episodes in cancer patients may enhance the detection rate of transient bacteremias. Both *H influenzae* and *Strep pneumoniae* may be grown from the blood of febrile children without malignancy who are seen in the outpatient setting.[5]

The incidence of bacteremias due to these organisms in the general population is unfortunately not available for comparison. However, the incidence of meningitis was recently reported by the Center for Disease Control to be 1.24/100,000 population/year for *H influenzae* and 0.6/100,000/year for *Strep pneumoniae*. The corresponding incidence rates in children younger than 2 years of age were 16 and 1/100,000/year.[6] In addition to the five patients with bacteremic meningitis described in this report, we observed six patients with nonbacteremic meningitis, five due to *H influenzae* type b and one due to *Strep pneumoniae*. Thus, the incidence of meningitis in these cancer patients followed up for a total of 4,196 years (Table 2) was 143/100,000 patient-years for *H influenzae* and 119/100,000 patient-years for *Strep pneumoniae*. These incidence rates are substantially higher than those for the general population and even those for children younger than 2 years of age.

Although *H influenzae* type b and *Strep pneumoniae* are both encapsulated pyogens and cause a similar spectrum of diseases in normal children, striking differences between the epidemiologic features of the infections were found in immunocompromised patients (Table 3). Pneumococcal bacteremia typically occurred in children with acute leukemia in relapse, who had received several different chemotherapy regimens, and who were profoundly granulocytopenic from recent chemotherapy. In contrast, *H influenzae* bacteremia occurred in children whose underlying disease was in remission, who were receiving maintenance chemotherapy, and who had adequate numbers of granulocytes.

Children with pneumococcal bacteremia tended to have higher and more prolonged fever, a higher incidence of associated infections, and a higher mortality than did those with *H influenzae* bacteremia (Table 4). These differences probably reflect differences in the severity of the underlying illness rather than differences in pathogenicity of these organisms. Most deaths in both groups occurred in profoundly granulocytopenic patients and were related to concurrent infections or to superinfections with other bacteria or fungi.

The majority of recognized foci of infection were associated with the respiratory tract. Only one of the nine *H influenzae* bacteremias in this series was associated with a meningeal focus, compared with 50% of *H influenzae* bacteremias in the general pediatric population.[7,8] Two of nine (22%) *H influenzae* and 11 of 24 (46%) *Strep pneumoniae* bacteremias had no apparent focus of infection. Folland et al[9] also noted that a high proportion (40%) of pneumococcal bacteremias in cancer patients had no focus of infection, and that younger patients were particularly likely to have no apparent source. On the other hand, Burke et al noted that only 15 of 111 (14%) pneumococcal bacteremias in normal children had no focus of infection.[10] Seven of the 13 bacteremias of unknown source in the present series were associated with symptoms of gastrointestinal toxicity (oral mucositis, vomiting, abdominal pain, or diarrhea) and 12 of 13 with granulocytopenia. Chemotherapy-induced mucosal damage may have permitted these pathogens to invade the blood stream without causing a localized focus of infection. Another possibility is that a localized focus was present but unrecognized because of a decreased inflammatory response.

Whether a diminished concentration of specific antibody is involved in the pathogenesis of these infections is not known. In patients receiving chemotherapy for acute leukemia, hypogammaglobulinemia does develop,[11] and patients who have completed intensive chemotherapy for Hodgkin's disease have decreased levels of specific antibody to the capsular polysaccharides of *H influenzae*[12] and *Strep pneumoniae*.[13]

The high incidence of infections with *Strep pneumoniae* and *H influenzae* suggests that children with cancer are an important target population for bacterial polysaccharide vaccines prepared from these organisms. All but one of the children reviewed were older than 2 years and thus theoretically able to respond to polysaccharide vaccines. If effective, the currently licensed pneumococcal vaccine would have protected nine of ten children whose strains were typed in this series, and 36 of 52 patients (69%) in Folland's series. A vaccine

against *H influenzae* type b might also have prevented eight of the nine episodes of bacteremia with this species.[14] Since most episodes of bacteremia occurred during active anticancer therapy, immunization should optimally be given at diagnosis or early during treatment. This approach is not without risk since the administration of antigen concurrently with chemotherapy may induce tolerance rather than an immune response.[15] Therefore, immunization of cancer patients cannot be routinely recommended until additional studies show that they can develop an adequate antibody response and can maintain antibody levels during prolonged chemotherapy. Ultimately, it would also be desirable to demonstrate protective efficacy in this population.

This investigation was supported by National Institutes of Health grants CA-19589, CA-09172, and CA-17979.

Mary Ellen Shea, RN, gave assistance with the chart review, Michael Gero, MS, provided computer printouts, and Stephen Sallan, MD, Myron Levin, MD, and Jerome Klein, MD, critically reviewed the manuscript.

Porencephaly From Periventricular Intracerebral Hemorrhage in a Premature Infant

Joseph F. Pasternak, MD; John F. Mantovani, MD; Joseph J. Volpe, MD

• **In two thirds of the premature infants who survived large periventricular intracerebral hemorrhage, a porencephalic cyst developed at the site of parenchymal hemorrhage. The porencephaly seems to develop as a result of local parenchymal destruction by the hemorrhage itself. These cysts can occur in the absence of posthemorrhagic hydrocephalus or increased intracranial pressure. Three of four infants who were observed for at least five months had lateralized motor deficit that corresponded to the cyst.**

(*Am J Dis Child* 134:673-675, 1980)

Cavitations within the cerebral hemisphere may be the result of a developmental aberration or an injury from a variety of sources. The term schizencephaly is used for the former lesions.[1] The destructive lesions are designated by a variety of terms, but encephaloclastic porencephaly (hereafter referred to as porencephaly) is the most appropriate, especially for single, cystic cerebral lesions. Porencephaly may result from diverse destructive influences, occurring usually in the prenatal or early neonatal period, and consisting most commonly of vascular occlusion of hypoxic-ischemic insult.[2,3] Causes cited less commonly include focal encephalitis,[4,5] trauma,[6] and ventricular puncture.[7]

We believe that the role of periventricular intracerebral hemorrhage in the genesis of this lesion is greater than previously recognized. Thus, the complex of periventricular intracerebral-intraventricular hemorrhage has been shown recently to be a very frequent lesion in the premature infant.[8,9] The hemorrhage originates in the periventricular germinal matrix and usually ruptures into the ventricular system.[10] However, extension into the cerebral white matter is not unusual and may result in a large intracerebral hematoma. We have documented recently the evolution of such an intracerebral hematoma into a porencephalic cyst in five infants.

REPORT OF CASES

Case 1.—An infant was born after a 32-week gestation. Spontaneous labor was halted with terbutaline sulfate, but profuse vaginal bleeding associated with a decreasing maternal hematocrit reading necessitated a cesarean section. Birth weight was 1,780 g and the Apgar scores at one and five minutes were 4 and 6, respectively. Severe respiratory distress developed in the delivery room and eventually required assisted ventilation. On the third day of life, the CSF was grossly bloody with a hematocrit reading of 8% and a protein concentration of 384 mg/dL. Computerized tomography (CT) the next day demonstrated an intraventricular hemorrhage (Fig 1). Progressive ventricular dilation developed despite daily lumbar punctures. The initiation of oral glycerin therapy resulted in stabilization of ventricular size. At 5 months of age, developmental progress seems normal and there are no focal deficits. Follow-up CT scans showed the development of a right frontal porencephalic cyst (Fig 2).

Case 2.—An infant was born after a 34-week gestation complicated by maternal ingestion of birth control pills for the first 4½ months. Spontaneous labor was not halted by terbutaline and the infant was delivered by cesarean section. Birth weight was 1,880 g and Apgar scores at one and five minutes were 9 and 10, respectively. Severe respiratory distress developed in the first 24 hours and required ventilatory assistance. On the third day of life, the CSF contained 6,400/cu mm RBCs and a protein concentration of 900 mg/dL. Alternate-day lumbar punctures were performed and on postnatal day 18 a CT scan showed moderate ventricular dilation and a right frontal porencephaly. Progressive ventricular dilation occurred despite glycerin therapy and a ventriculoperitoneal shunt was placed at 4 months of age. The child's psychomotor development was delayed and he had a left hemiparesis with greater involvement of the upper extremity. Increasing congestive heart failure secondary to bronchopulmonary dysplasia resulted in death at age 14 months. Postmortem examination showed a large, porencephalic cyst in the right frontal region (Fig 3).

Case 3.—A female infant was born after a 30-week gestation. Birth weight was 1,400 g and Apgar scores at one and five minutes were 4 and 6, respectively. By 3

hours of age, respiratory distress, hypothermia, bradycardia, and apnea had developed, and the child required assisted ventilation. The CSF contained 269,000/cu mm RBCs and a protein concentration of 1,520 mg/dL. Progressive ventricular dilation was not prevented by daily lumbar punctures or glycerin therapy, and she required a ventriculoperitoneal shunt at 5 months of age. Initial CT scan on postnatal day 13 showed a large intraventricular hemorrhage with a large right frontal, intraparenchymal hematoma (Fig 4). Subsequent CT scans demonstrated the development of right frontal porencephaly (Fig 5). At 5 months of age, she had severe psychomotor delay and a left hemiparesis with hyperreflexia and spasticity.

Case 4.—A male infant was born after a 30-week gestation. Birth weight was 1,380 g and the one- and five-minute Apgar scores were 7 and 9, respectively. In the first 24 hours of life, respiratory distress, hypotension, stupor, and a full anterior fontanelle developed. The CSF obtained on the first day of life had a hematocrit reading of 15%. A CT scan on the eighth postnatal day showed a large intraparenchymal hemorrhage in the left frontal area, a smaller hemorrhage in the right thalamus, and subarachnoid blood (Fig 6). Subsequent CT scans documented the resolution of the intraparenchymal hemorrhage and the appearance of a left frontal porencephalic cyst (Fig 7). At five months of age, he demonstrated moderate developmental delay and a subtle right hemiparesis, involving the face more than the extremities.

Case 5.—A female infant was the second born of twins after a 29-week gestation. She was delivered from a double footling breech presentation and Apgar scores at one and five minutes were 3 and 7, respectively. Birth weight was 1,240 g. Mild res-

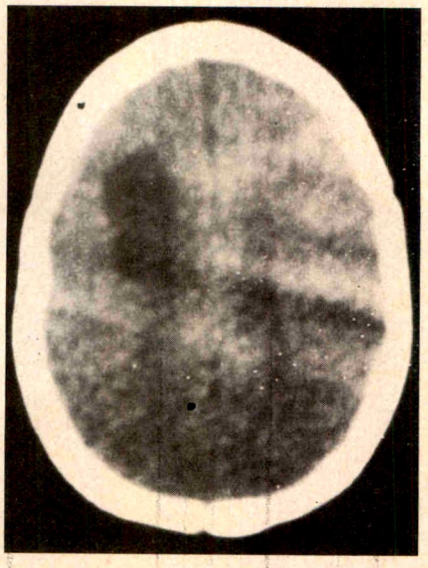

Fig 7.—Left frontal porencephaly at age 4 months.

piratory distress developed that required oxygen supplementation for 48 hours (maximum oxygen concentration, 40%). On the second day of life, the CSF contained 6,000/cu mm RBCs and a protein concentration of 900 mg/dL. A CT scan on the fifth day of life showed intraventricular hemorrhage, especially prominent on the right side, with extension into the right caudate nucleus. Subsequent CT scans documented the development of a small right frontal porencephalic cyst. At 1 month of age, results of physical examination were normal and without evidence of a focal deficit.

COMMENT

Yakovlev and Wadsworth[1] separated cystic cerebral lesions into schizencephaly and encephaloclastic cysts, ie, porencephaly. Schizencephaly appeared to be a true developmental defect of cerebral organogenesis, characterized by a restricted failure of formation of the cortical mantle. Heterotopic gray matter, polymicrogyria, and aberrant fibers were associated developmental abnormalities. These defects were generally bilateral and symmetric and communicated with the subarachnoid space. The typical encephaloclastic cyst, ie, porencephaly, is a fluid-filled defect within the cerebral parenchyma, the result of a destructive process. These cysts are usually unilateral and may communicate with the ventricular system. Most workers have attributed encephaloclastic porencephaly to occlusive arterial[2] or venous[3] disease.

Deonna et al[11] found unilateral cystic cavities that communicated with the ventricular system in four of ten infants with posthemorrhagic hydrocephalus. The diagnosis of intracranial hemorrhage in the neonatal period was made on the basis of the clinical syndrome and CSF findings. Unfortunately, the size and location of the intracranial blood was unknown in their patients, although each had an acute neurologic deterioration, suggesting that they had large hemorrhages.[10] The authors attributed the cystic lesions to ischemic injury to the periventricular white matter in combination with increased pressure within the ventricular system.

Our cases demonstrate that porencephaly may develop at the site of the intraparenchymal hemorrhage. In all four of our cases that have had demonstrable intracerebral hemorrhage by CT scan, the porencephalic cyst developed at the same site during the ensuing weeks. We believe that the pathogenesis of the porencephaly relates to the focal cerebral destruction by the hemorrhage rather than ischemia-induced periventricular encephalomalacia. Although increased intraventricular pressure is not necessary for the evolution of the porencephaly (case 4), such pressure may contribute to the development of the lesion. Thus, when intraventricular pressure is elevated and periventricular gray structures have been destroyed by the hemorrhage, herniation of the ventricular system into the cerebral mantle will be possible. These nuclear structures, eg, head of the caudate nucleus, tend to restrict dilation of the ventricles, as demonstrated by the usual occurrence in posthemorrhagic hydrocephalus of marked dilation of occipital horns and near normal size of the frontal horns of the lateral ventricles.[10]

Porencephaly subsequent to periventricular-intracerebral hemorrhage of the premature infant may be a relatively common lesion. Burstein et al[12] have described a similar evolution of intracerebral hemorrhage to porencephaly, although they did not include a clinical description. Our five infants were seen during an 18-month period and constituted two thirds of our surviving infants with large periventricular intracerebral-intraventricular hemorrhage. Moreover, the focal cerebral lesion contributes to the morbidity observed as a sequel to periventricular hemorrhage; indeed, focal motor deficit contralateral to the porencephaly was observed frequently in our cases early in infancy. Other clinical correlates, such as intellectual function, await longer-term follow-up.

The Effect of Circumcision on Transcutaneous Po_2 in Term Infants

David J. Rawlings, MD; Patricia Anne Miller; Rolf R. Engel, MD

• To assess the effect of pain on Pao_2 in newborns, transcutaneous Po_2 ($tcPo_2$) was monitored in ten healthy male infants undergoing circumcision. The $tcPo_2$ was seen to decrease to a lower level with pain and to remain low with continuing pain. After the circumcision, the $tcPo_2$ increased to levels equal to or exceeding those of the preoperative baseline period. Close concordance of $tcPo_2$ above and below the waist demonstrated no right-to-left shunting through the ductus arteriosus.

(*Am J Dis Child* 134:676-678, 1980)

Investigators[1-5] who have correlated Pao_2 with transcutaneous Po_2 ($tcPo_2$) have obtained blood samples from indwelling arterial lines because of concern that the pain of an arterial puncture may disturb oxygenation. To further define the effect of pain on $tcPo_2$, normal male infants were monitored during circumcision. Simultaneous monitoring of the $tcPo_2$ over the right upper side of the chest and left lower part of the abdomen enabled us to evaluate the possibility of right-to-left shunting through the ductus arteriosus during the procedure of circumcision.

SUBJECTS AND METHODS

Ten healthy male infants were circumcised at 48 to 72 hours of age after obtaining informed consent from the parents. All were born at term with one-minute Apgar scores greater than 7 and a mean birth weight of 3,350 g. Neither heart murmurs nor abnormal femoral artery pulses were detected immediately prior to circumcision.

The procedure consisted of the following: about five minutes of cleaning the penis with povidone-iodine (Betadine) solution; adhesion lysis between glans and foreskin; dorsal foreskin clamping with forceps for

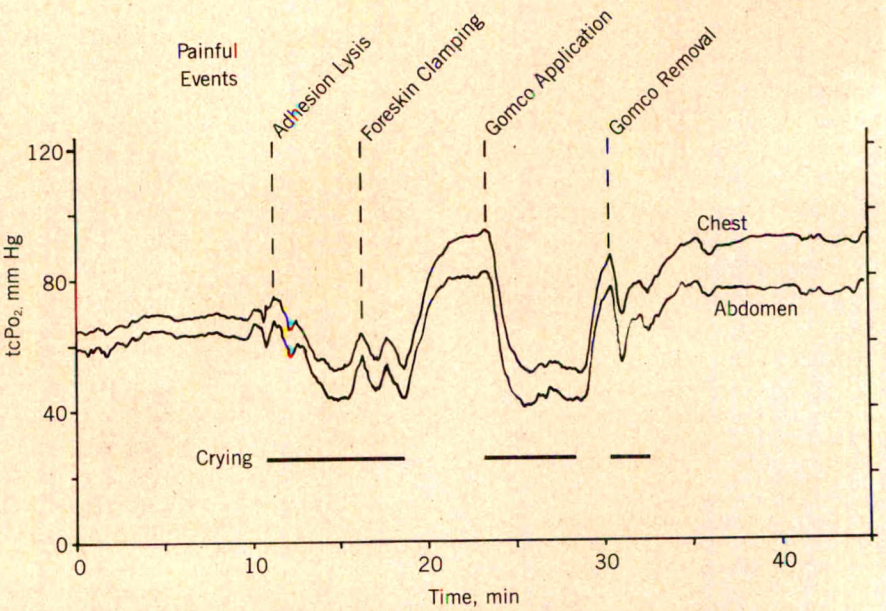

Fig 1.—Continuous recording of transcutaneous Po_2 ($tcPo_2$) on chest and abdomen during circumcision. Abdominal tracing was shifted down 8 mm Hg for clarity.

†Significantly ($P < .05$) greater than preoperative value.

two to four minutes, followed by forceps removal and division of the crushed skin. A bloodless circumcision clamp (Gomco) was applied for five minutes before the foreskin was amputated. To discern the effect for each of the four painful manipulations, the interval from adhesion lysis to circumcision clamp removal was extended to 20 minutes.

Throughout the study, a radiant overhead warmer was used to maintain the abdominal skin temperature at 36.0 °C. A nipple was offered for nonnutritive sucking. The period of continuous monitoring included at least 20 minutes before and after the circumcision. Transcutaneous oxygen electrodes (TCM1 Radiometer) were affixed below the right clavicle and to the left of the umbilicus. Both electrodes were thermally insulated with expanded rigid polystyrene plastic caps so that the electrode heat consumption served as an indirect measure of local blood flow.[6] Respiratory and heart rates were monitored with vital signs modules. All parameters were recorded continuously on a potentiometric recorder. The $tcPo_2$ electrodes were interchanged at the end of the monitoring periods to help separate instrumentation from physiologic differences. Average values were obtained from planimetry of the tracings.[7] Statistical comparisons used two-tailed paired t testing.

RESULTS

Each of the studies demonstrated close concordance between the $tcPo_2$ tracings from the chest and abdomen (Fig 1). None of the infants showed a significant difference between chest and abdominal $tcPo_2$ during quiet or crying intervals. Both $tcPo_2$ tracings decreased with pain and remained at a lower level until crying ceased. During brief respites from crying, the $tcPo_2$ rebounded partially, and with longer quiet periods, the preoperative $tcPo_2$ was often exceeded.

The change in $tcPo_2$ after the four painful procedures involved in circumcision was plotted for each of the ten subjects (Fig 2). There was a significant decrease in $tcPo_2$ for all 40 events considered together ($P < .001$) and for three of the four individual categories. The average decrease in the $tcPo_2$ was 15 mm Hg for adhesion lysis, less than 1 mm Hg for foreskin clamping, 13 mm Hg for circumcision clamp application, and 19 mm Hg for circumcision clamp removal. The negligible response to foreskin clamping probably reflects the absence of a quiet interval before this event in contrast to adhesion lysis and circumcision clamp removal, both of which followed manipulation-free intervals of five or more minutes, and circumcision clamp application, which was preceded by variable freedom from stimulation. The average postevent $tcPo_2$ for each of the four manipulations was not significantly different than that for any of the other three.

The average $tcPo_2$ was increased during the postoperative period. ($P < .05$, Table). Electrode heat consumption remained constant throughout the study, with no difference between chest and abdominal electrodes. The average heart and respiratory rates were higher during the intraoperative and postoperative periods as compared with the preoperative interval ($P < .05$, Table).

COMMENT

Circumcision in neonates has been shown to affect adrenal cortical func-

tion,[8] immediate postoperative behavior,[9-11] and possibly long-term behavior.[12] The present study demonstrates that circumcision also affects the heart rate, respiratory rate, and $tcPo_2$ both during and immediately after the procedure. The observed decrease in $tcPo_2$ with pain might result from momentary decreases in alveolar ventilation during crying. Right-to-left shunting at the atrial level, with crying, as shown by Lind et al[13] during the first 2 weeks of life, is also a possible explanation. The close concordance of chest and abdominal $tcPo_2$ indicates that despite vigorous crying, right-to-left shunting through the ductus arteriosus did not occur in our sample of 2- to 3-day-old, term male infants. The absence of hypoxic symptoms in this group of term infants is in accord with the prediction that healthy infants should not be compromised by a transient decrease of 20 mm Hg in $tcPo_2$.

The 10 mm Hg increase in mean $tcPo_2$ after the circumcision could reflect increased minute ventilation in lungs fully expanded from recent crying. Although Martin et al[5] have also observed mean $tcPo_2$ levels less than 80 mm Hg in healthy infants, it is possible that an allowance should be made for the thicker skin of term infants since the electrode temperature of 44 °C and the warm-up period of 20 minutes were based on correlation (r = .95) between $tcPo_2$ and Pao_2 in premature infants.

The response to pain by each individual infant was surprisingly consistent. That is, some infants had abrupt decreases in $tcPo_2$ and increases in heart and respiratory rates with each of the painful stimuli while other infants repeatedly had attenuated responses. These individual variations in the response to pain underline the limited reliability of arterial punctures for assessment of resting Pao_2. Since the $tcPo_2$ often exceeded baseline values after crying ceased, there is also the possibility that delay in drawing an arterial blood sample could result in obtaining a Pao_2 that is greater than the baseline.

Aerobic and Anaerobic Bacteriology of Pilonidal Cyst Abscess in Children

Itzhak Brook, MD, MS; Kathryn D. Anderson, MD; Guido Controni, MS; William J. Rodriguez, MD, PhD

• **Aspirates of pus from pilonidal abscesses in 25 children were studied for aerobic and anaerobic bacteria. A total of 76 isolates (63 anaerobic and 13 aerobic) were recovered from the patients, accounting for 2.52 anaerobes and 0.52 aerobes per specimen. Anaerobic organisms were recovered from all the specimens, and in eight cases (32%) they were mixed with aerobic organisms. The predominant anaerobic organisms were *Bacteroides* sp (36 isolates, including ten *B fragilis* group and ten *B melaninogenicus* group), Gram-positive anaerobic cocci (16), *Fusobacterium* sp (five), and *Clostridium* sp (four). The predominant aerobic organisms were *Escherichia coli* (four) and group D streptococci, α-hemolytic streptococci, and *Proteus* sp (two of each). We believe this study is the first to demonstrate the mixed anaerobic and aerobic bacteriology of pilonidal cyst abscesses in children.**

(*Am J Dis Child* 134:679-680, 1980)

Pilonidal sinus is commonly encountered in pediatric patients, especially in the adolescent age group. Pilonidal sinus infection is often protracted, causes local irritation, and may in rare cases lead to serious complications, such as bacteremia or meningitis. To our knowledge, the bacteriologic features of infected pilonidal cyst in children have never been studied with anaerobic and aerobic bacteriology techniques. Most of the data in the literature are derived from studies done in adults.[1] This study was designed to determine the aerobic and anaerobic bacteriologic features of pilonidal cyst abscess in pediatric patients.

Reprint requests to Infectious Diseases and Clinical Microbiology Laboratory, Children's Hospital National Medical Center, 111 Michigan Ave, NW, Washington, DC 20010 (Dr Brook).

SUBJECTS AND METHODS

The 25 children included in the study were treated at Children's Hospital National Medical Center, Washington, DC, for a pilonidal cyst abscess that required surgical drainage. Mean age of the patients was 7 years and 3 months (range, 10 months to 14 years). Thirteen were girls. Eight of the patients received antimicrobial therapy prior to sample collection.

Cultures were obtained by direct needle aspiration of the purulent content into a syringe that was immediately sealed, or by a swab that was dipped in the pus and introduced into anaerobic transport media. The specimens were transported to the bacteriology laboratory and inoculated within ten to 30 minutes after collection.

Sheep blood (5%), chocolate, and MacConkey's agar plates were inoculated for the isolation of aerobic organisms. The plates were incubated at 37 °C aerobically (MacConkey's) and under 5% CO_2 (blood and chocolate), and examined at 24 and 48 hours. For the isolation of anaerobes, the specimens were plated onto prereduced vitamin K_1-enriched *Brucella* blood agar, an anaerobic blood agar plate containing kanamycin sulfate (75 μg/mL) and vancomycin hydrochloride (7.5 μg/mL), an anaerobic blood plate containing phenylethyl alcohol, and an enriched thioglycolate broth.[2] These media were incubated inside anaerobic jars at 37 °C, and examined at 48 and 96 hours. The thioglycolate broth was incubated for 14 days. Anaerobes were identified by techniques previously described.[2] Aerobic bacteria were identified by means of conventional methods.[3] β-Lactamase activity was determined on all isolates with use of the chromogenic cephalosporin analog 83/312 methodology.[4]

RESULTS

All 25 specimens yielded bacterial growth that included anaerobic organisms. Mixed aerobic and anaerobic bacteria were present in eight patients (32%), and anaerobic bacteria only were present in 17 of the patients (68%). A total of 76 anaerobic and aerobic isolates were recovered from the patients, accounting for 3.04 isolates per specimen (2.52 anaerobes and 0.52 aerobes per specimen) (Table).

A total of 63 anaerobic isolates were recovered from the patients. The predominant anaerobes recovered, in descending order of frequency, were as follows: *Bacteroides* sp (36 instances, including ten *B fragilis* group and ten

B melaninogenicus group), anaerobic Gram-positive cocci (16), *Fusobacterium* sp (five), and *Clostridium* sp (four).

A total of 13 aerobic isolates were recovered. The predominant aerobic isolates were *Escherichia coli* (four), and group D streptococci, *Proteus* sp, and α-hemolytic streptococci (two of each). There was no consistent pattern of combination; however, in every instance in which *Bacteroides* sp was isolated, Gram-positive anaerobic cocci were present.

β-Lactamase production was detected in 12 isolates. These included all isolates of *B fragilis* (10) and *Staphylococcus aureus* (one) and two of the ten isolates of *B melaninogenicus*.

COMMENT

This study discusses our experience in the isolation of aerobic and anaerobic bacteria from pilonidal cyst abscesses in children. To the best of our knowledge, no such data relating to pediatric patients have been published.

Recently, Finegold[1] summarized 13 publications dealing with the bacteriologic characteristics of infected pilonidal cyst in adults. The most frequent isolates reported in those studies were various *Bacteroides* sp, including *B fragilis*, anaerobic Gram-positive cocci, and *Clostridium* sp. A recent report[6] presented the bacteriologic features of pilonidal cyst abscess in 11 adults. Anaerobic organisms, such as *Bacteroides* sp and Gram-positive anaerobic cocci, were the predominant isolates. Gram-negative enteric bacteria and *S aureus* were not present.

Our bacteriological study of pilonidal cyst abscess in children demonstrated that anaerobic organisms, the predominant isolates in these infections, outnumber aerobes in a ratio of 5 to 1. In contrast to other investigators,[5,6] we have been able to retrieve Gram-negative aerobic bacilli in five instances. Like other investigators, we did not find *S aureus* to be a predominant isolate in this type of infection.

The isolation of anaerobic bacteria mixed with aerobic and facultative organisms at that site is not surprising since anaerobes are the predominant organisms in the gastrointestinal tract where they outnumber aerobes in the ratio of 1,000:1.[7] Since anaerobic bacteria are frequently associated with pilonidal abscess in pediatric patients, the physicians should consider their presence if antimicrobial therapy is used. Gram staining of aspirated pus and appropriate aerobic and anaerobic techniques can help the physician select proper therapy. Since some of the anaerobes are resistant to penicillin, therapy should also include appropriate coverage of those organisms. Surgical drainage is still the therapy of choice. However, the presence of penicillin-resistant anaerobic bacteria, such as *B fragilis*[8] and some strains of *B melaninogenicus*,[8,9] may warrant the administration of appropriate antimicrobial agents, such as clindamycin, chloramphenicol, cefoxitin, carbenicillin disodium, ticarcillin disodium, or metronidazole.

Leslie Calhoun, MS, Linda Harteker, MS, and the staff of the clinical microbiology laboratory at the Children's Hospital National Medical Center cooperated in this study.

Acute Glomerulonephritis and Streptococcal Skin Lesions in Eskimo Children

Harold S. Margolis, MD; Milton K. W. Lum, MD; Thomas R. Bender, MD, MPH; Sarah L. Elliott, RN; MaryAnne Fitzgerald; Annette P. Harpster, RN

• Poststreptococcal acute glomerulonephritis often follows impetigo and can occur in epidemics. From 1975 through 1977, an epidemic of poststreptococcal acute glomerulonephritis occurred in Alaska. Fifty children required hospitalization, while 25 less seriously ill children were treated as outpatients. Sixty-seven percent of these 75 children had direct evidence of recent skin infections. Serotypes 49-14 and NT-14 were the most common streptococcal isolates. In villages in the epidemic area, approximately 15% of children had impetigo and more than 60% of lesions cultured were positive for group A streptococci. Impetigo rates in the epidemic area were similar to those found in nonepidemic areas. However, the introduction of the nephritogenic streptococcal serotypes not recently present in this population apparently led to the development of the epidemic.

(*Am J Dis Child* 134:681-685, 1980)

Impetigo usually occurs when mild skin trauma becomes secondarily infected with group A streptococci.[1] Although suppurative complications from impetigo are rare,[2] the nonsuppurative complication of acute glomerulonephritis may frequently occur following infections with certain serotypes of streptococci.[3] Classically, impetigo has been thought to be a disease of warm or temperate climates,[1,2,4] although it has been reported in arctic regions.[5] Beginning in 1975, an epidemic of impetigo-related poststreptococcal acute glomerulonephritis occurred in Eskimo children living in southwestern Alaska, and had considerable impact on the health care facilities and families living in that region.

Approximately 15,000 Yupik-speaking Eskimos live in 53 villages located on the delta of the Yukon and Kuskokwim rivers in southwestern Alaska. Primary health care in each village is provided by trained community health aides, and patients with serious illness are referred to the 42-bed Public Health Service Alaska Native Hospital located in the town of Bethel, the transportation center of the region.

A mail-in streptococcal culture program that included grouping and typing of isolates had been introduced in the area in 1971 as one part of a program to reduce the incidence of acute rheumatic fever. The presence of this program in the region prior to and during the epidemic of acute glomerulonephritis provided a unique opportunity to describe the epidemic features of streptococcal disease in remote communities in relation to the occurrence of acute glomerulonephritis. We describe the epidemic and its clinical features and relate the epidemic to the distribution of strepto-

coccal disease and pyoderma in Eskimo children.

METHODS

Sources of Data

The medical record system of the Alaska Area Native Health Service was used to identify cases of poststreptococcal glomerulonephritis during the pre-epidemic period July 1971 through September 1975. Charts were reviewed and pre-epidemic rates of poststreptococcal glomerulonephritis were established. The following were determined in order to compare the occurrence of impetigo in the epidemic area served by the Bethel hospital with nonepidemic areas. First, the prevalence of impetigo among children aged 6 months through 14 years was determined in 13 Eskimo villages through active screening during physical examinations conducted in the field. Of the 13 villages, six were in the Bethel region, while seven were in the Bristol Bay region, an area considered nonepidemic. In addition, the frequency of outpatient visits for impetigo at the Alaska Native Health Center in Fairbanks, 854 km northeast of the epidemic area, were compared with those for the Bethel facility.

Clinical and Laboratory Examinations

Children who came to the clinic and were suspected of having poststreptococcal acute glomerulonephritis during the epidemic period were evaluated by measurement of blood pressure, chest roentgenogram, and serial measurements of weight. Routine clinical laboratory determinations included urinalysis, complete blood cell count, and measurements of serum electrolytes, BUN, creatinine, ESR, quantitative urine protein, and creatinine clearance. The C3 level was determined by radial immunodiffusion. Antistreptolysin O (ASO) determinations were performed routinely on hospital admissions. Sera from patients were stored at −70 °C, and at a later date ASO and antideoxyribonuclease B (ADN-B) determinations were performed on these specimens with use of microtitration techniques[6,7] and a 60, 85 dilution scheme. For Alaskan Eskimos, the upper limits of normal for ASO and ADN-B were determined from an age-stratified group of 80 children. These children, participants in the streptococcal surveillance program, had no positive cultures for streptococci in spite of repeated testing during a one-year period and also had no change (<0.3 log) in antibody titer for this same period. The calculated upper limit of normal[8] for ASO (ages 2 to 14 years) was 170; for ADN-B (ages 2 to 14 years), it was 480. The normal upper limits for both ASO and ADN-B resemble those reported for uninfected children in Alabama by Dillon and Avery.[9]

Throat cultures were obtained, and impetiginous lesions were cultured after the scab was removed. The cotton swabs were placed in silica gel[10] and mailed to the Anchorage laboratory, where they were incubated at 37 °C for four to six hours in Todd-Hewitt broth. An inoculum of the broth was used to prepare sheep blood-agar pourplates, which were then incubated at 37 °C for 18 to 20 hours. *Streptococcus*-like colonies were subcultured and grouped by the Lancefield method.[11] Group A extracts were typed by T-agglutination and M-precipitin tests[12] with antiserum provided by Bureau of Laboratories, Center for Disease Control, Atlanta.

Definitions

A case of poststreptococcal acute glomerulonephritis was defined as a patient with recent onset of hematuria plus at least two of the following findings: hypertension, edema, signs of vascular overload on chest roentgenogram (cardiomegaly, effusions, increased pulmonary vascularity), hypocomplementemia, or evidence of recent streptococcal infection (positive culture, history of impetigo or pharyngitis, or elevated ASO titer).

RESULTS

Acute Glomerulonephritis

Epidemiologic Findings.—Seventy-five children in 50% of the villages in the Bethel region fulfilled the case definition for poststreptococcal glomerulonephritis from October 1975 through December 1977. Only seven cases were identified through chart review for the preceding years. Fifty patients (67%) were hospitalized because of symptoms of volume overload, and 25 were treated as outpatients. All patients were children under 15 years of age. The mean age was 6 years 10 months (range, 19 months to 14 years). Both sexes were equally affected.

Clinical and Laboratory Findings.—Hypertension was present in 68% of the cases (94% of hospitalized patients and 16% of outpatients). Among inpatients, the average weight loss from diuresis was 7.7% of the initial body weight (range, 3% to 15%). The mean duration of hospitalization was seven days, and patients were discharged when there was no further evidence of hypertension and there were indications that diuresis had begun. Many

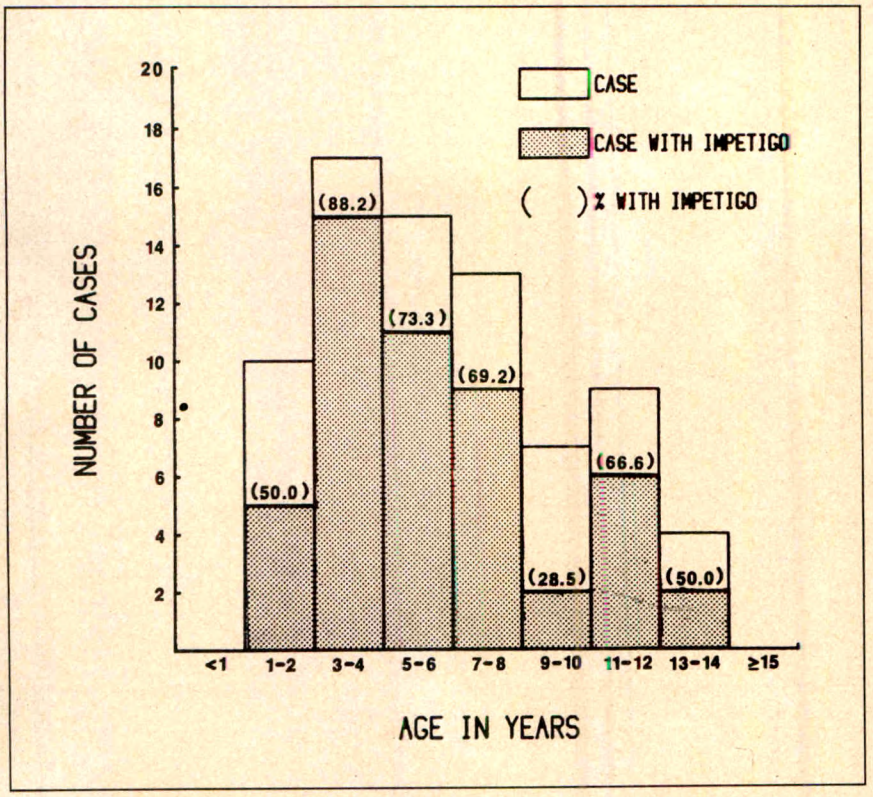

Fig 1.—Age-specific frequency of impetigo in relation to age distribution of Eskimo children with poststreptococcal acute glomerulonephritis: number of cases of acute glomerulonephritis (open portion); number of cases of impetigo (shaded portion); age-specific frequency of impetigo (parenthetical numbers).

children were found to have abnormalities of urine sediment and serum (Table 1). The mean creatinine clearance for 24 inpatients was 55.5 mL/min/1.73 sq m (range, 13 to 111 mL/min/1.73 sq m). Chest roentgenograms showed abnormal findings in 34 of 43 inpatients and in nine of 19 outpatients. Cardiomegaly, the most frequent abnormality documented by roentgenogram, occurred in 72% of those studied. In those with cardiomegaly, other abnormalities also were found, including increased pulmonary vascularity (19%) and pleural effusions (16%). Fifteen percent of all roentgenograms showed evidence of lobar consolidation, and in all but one case, this finding occurred in children without signs of volume overload.

Streptococcal Isolates and Serologic Findings.—Of the 75 children with acute glomerulonephritis, 50 (67%) had evidence of impetigo on physical examination (32 children) or by history (18 children), and the age group most affected in the epidemic (3 to 4 years) was the age group most likely to have skin lesions (Fig 1). Of the 32 children with evidence of impetigo on physical examination, 21 (65%) had skin lesions positive for group A streptococcal organisms, and while impetigo cultures from the remaining 11 children were negative, one had a positive throat culture. Of the 18 children with a history of impetigo (but who were free of skin lesions at the time of examination), eight had throat cultures positive for group A streptococcal organisms. Of the 25 children without evidence of impetigo either by history or by examination, eight had a positive throat culture. Typing of the available group A streptococcal isolates from all sites revealed that 25 were non-M-typable T-type 14 (NT-14), six were M-type 49 T-type 14 (49-14), two were NT-B3264, and one was NT-3/13/B3264. Of the remaining 17 children with neither evidence of impetigo nor a positive throat culture, all but one had serologic evidence of recent streptococcal infection.

Both ASO and ADN-B titers were measured on 35 of the children with acute glomerulonephritis. The geometric mean for the ASO titers was 196 (range, <60 to 960) and 36% were above the upper limit of normal. The geometric mean for the ADN-B titers was 653 (range, 240 to 3,840) and 58% were abnormal. There were no differences between the titers of inpatients and outpatients. Overall, 69% of the ill children had at least one serologic test result that was abnormal.

Streptococcal Skin Infections

Epidemiologic Features.—From 1974 through 1977, impetigo accounted for an average of 0.8% of the total outpatient visits at the Bethel hospital. At the Alaska Native Health Center in Fairbanks, 854 km northeast of the epidemic area, impetigo accounted for 1.4% of the outpatient visits during this same time period. The yearly rates in both facilities did not vary significantly during the four-year period. In both areas, seasonal variation in outpatient visits for impetigo occurred, but the variation was similar in both facilities (Fig 2).

When 593 children were surveyed during January 1976 in six Bethel area villages initially involved in the epidemic, 79 (13%) had impetigo. These same children were studied when the epidemic had ended in their villages (September 1976), and of 434 examined, 63 (15%) had impetigo. Of the 535 Bristol Bay area children not involved in the epidemic when surveyed during August 1977, a total of 104 (19%) had skin infections.

Preschoolers were the age group most often seen with impetigo at the hospital outpatient department; however, in the village populations surveyed, impetigo was not limited to children in any one age group (Table 2).

Streptococcal Isolates.—Cultures for the isolation of streptococci were obtained from impetiginous lesions of children in the villages surveyed in the area around Bethel. Of 63 children cultured in January 1976, 80% were positive for group A streptococci, and during September 1976, when 55 children were cultured, 52% had positive cultures. From 1976 through 1977,

*N indicates number of group A isolates typed.
†NT indicates nontypable.
‡Other serotypes included were NT 6/23, NT 13, NT 12, NT 6, NT 5/27/44, 1-1, 4-4.

1,246 cultures of impetiginous lesions from children in Bethel and surrounding villages were submitted through the mail-in streptococcal surveillance program, and 69% were positive for group A streptococci. The nephritogenic strain, T-type 14, often in association with M-type 49, was the most common serotype identified (Table 3). In the five years prior to September 1975, this serotype had not been found in thousands of cultures (mostly throat cultures) collected throughout Alaska.

COMMENT

Epidemic acute glomerulonephritis in association with impetigo has been reported from both tropical[4] and temperate regions.[3,13,14] Although impetigo has previously been reported among children living in the Arctic,[5] there have been no other published reports of the occurrence of epidemic glomerulonephritis in the Arctic. Children with glomerulonephritis seen at the Bethel hospital during this epidemic had a clinical picture similar to that reported during epidemics occurring in other locales,[4,13,14] and signs of volume overload predominated in the children with the most serious illness.

Evidence of an antecedent streptococcal infection was documented in all but one child. The skin was the predominant site of infection, and ADN-B titers were elevated more often than ASO titers.

The rate of impetigo, its seasonal variation, and the age distribution of those affected are similar in Alaska to findings reported for temperate regions,[15,16] even though the climates are different. Eskimo children have a considerable amount of streptococcal skin colonization and skin trauma from insect bites, scabies, and frostbite, all of which may predispose them to impetigo. Other studies of children with poststreptococcal acute glomerulonephritis have shown that this disease is strongly associated with infection of the skin.[4,13,17] This was our finding clinically and we were also able to demonstrate through village surveys that the age-specific rates of impetigo in children with acute glomerulonephritis were higher than the age-specific prevalence of impetigo present in the general population. However, there was no evidence that impetigo rates themselves changed markedly before or after the epidemic or that rates differed in regions with or without epidemic acute glomerulonephritis. As the epidemic progressed, fewer of the children with acute glomerulonephritis had impetiginous lesions that were positive when cultured for streptococcal organisms. This decrease in isolates may have been due to the development of a vigorous campaign that encouraged parents to bring their children to the clinic for early treatment of impetigo with systemic antibiotics.

Through our ongoing statewide streptococcal surveillance program, we had gathered evidence that the epidemic serotypes had not been present in the state for at least five years prior to the outbreak, a situation similar to that found at Red Lake.[13] Both the 49-14 and the NT-14 organisms isolated from the cases appeared as new introductions at about the same time. Preliminary laboratory evidence suggests that the NT-14 organism differs from the 49-14 serotype, implying that the NT-14 organism may be a new nephritogenic strain. Futher bacteriologic studies of these organisms are under way.

After the epidemic arose in the Bethel region, the implicated nephritogenic organisms eventually became established in various other parts of Alaska to nearly the same extent as they had been in the Bethel region. However, there was only a small increase in the occurrence of symptomatic cases of acute glomerulonephritis in these areas after the apparent spread of the epidemic serotype. The absence of an epidemic in the presence of impetigo infected with nephritogenic streptococci has been observed in Trinidad,[17] and additional study of the organisms observed in this phenomenon may further elucidate the pathogenesis of this disease.

The medical, nursing, and laboratory staff of the Public Health Service Alaska Native Hospital in Bethel and the Streptococcal Surveillance Program of the Yukon-Kuskokwim Health Corp provided assistance. George Brenneman, MD, Phillip Barrett, MD, Douglas Cowgill, MD, Quentin Fisher, MD, Robert Hurwitz, MD, Benjamin Marchello, MD, Raymond Shields, MD, Leslie Boss, MT (ASCP), Carol Conlon, MT (ASCP), and Patricia Porter, MT (ASCP), provided assistance. Richard R. Facklam, PhD, and Lewis W. Wannamaker, MD, studied the strains involved in the epidemic and provided confirmatory serotyping.

Brief Summary.
Consult the package literature for prescribing information.

Indications and Usage: Ceclor®(cefaclor, Lilly) is indicated in the treatment of the following infections when caused by susceptible strains of the designated microorganisms:

Otitis media caused by *Streptococcus pneumoniae (Diplococcus pneumoniae), Haemophilus influenzae,* staphylococci, and *S. pyogenes* (group A beta-hemolytic streptococci).

Appropriate culture and susceptibility studies should be performed to determine susceptibility of the causative organism to Ceclor.

Contraindication: Ceclor is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

Warnings: IN PENICILLIN-SENSITIVE PATIENTS, CEPHALOSPORIN ANTIBIOTICS SHOULD BE ADMINISTERED CAUTIOUSLY. THERE IS CLINICAL AND LABORATORY EVIDENCE OF PARTIAL CROSS-ALLERGENICITY OF THE PE CILLINS AND THE CEPHALOSPORINS, AND THERE ARE INSTANCES IN WHICH PATIENTS HAVE HAD REACTIONS TO BOTH DRUG CLASSES (INCL ING ANAPHYLAXIS AFTER PARENTERAL USE).

Antibiotics, including Ceclor® (cefaclor, Lilly), should administered cautiously to any patient who has demonstrated some form of allergy, particularly to drugs.

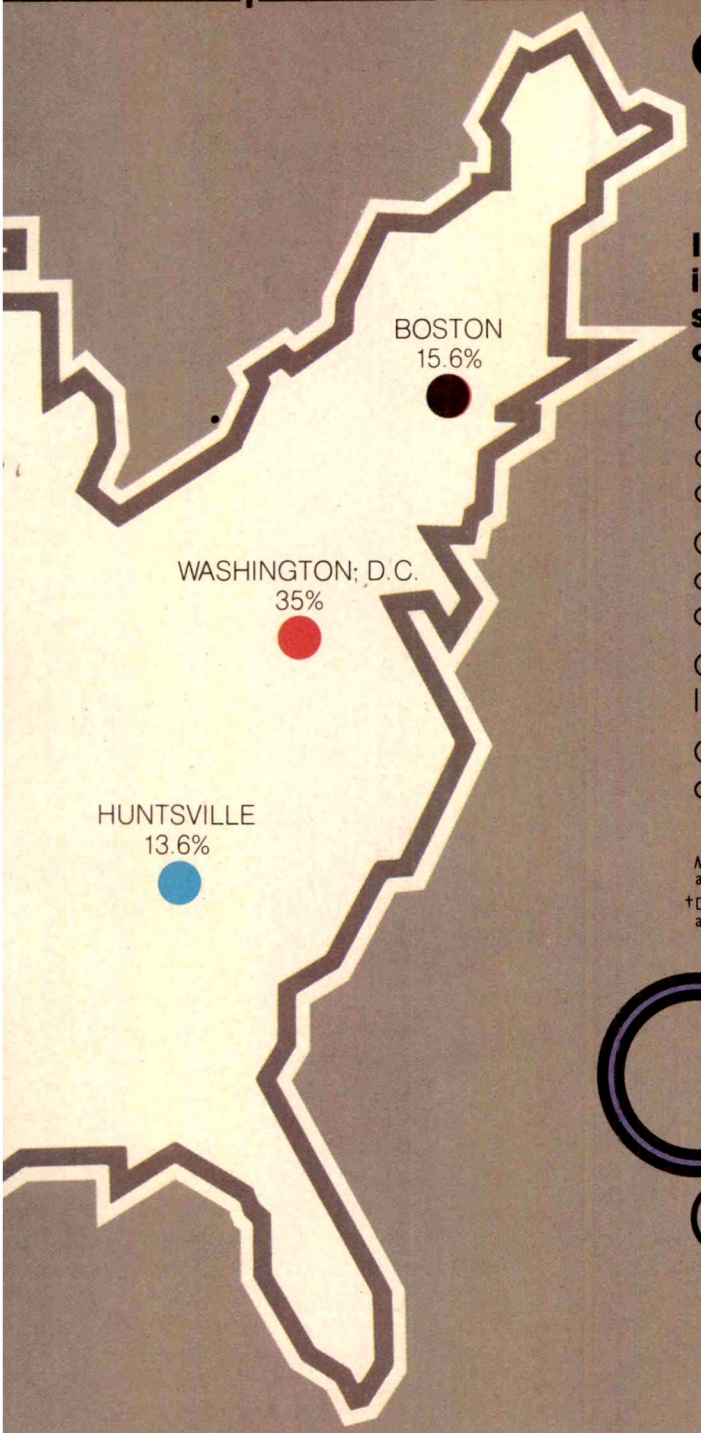
Precautions: If an allergic reaction to cefaclor occurs, t drug should be discontinued, and, if necessary, the pat should be treated with appropriate agents, e.g., pressc amines, antihistamines, or corticosteroids.

Prolonged use of cefaclor may result in the overgrow of nonsusceptible organisms. Careful observation of th patient is essential. If superinfection occurs during therapy, appropriate measures should be taken.

Positive direct Coombs tests have been reported dur treatment with the cephalosporin antibiotics. In hemato logic studies or in transfusion cross-matching procedu when antiglobulin tests are performed on the minor sid in Coombs testing of newborns whose mothers have received cephalosporin antibiotics before parturition, it

Haemophilus influenzae in otitis media...

a valid concern



In many areas of the country, increasing numbers of *H. influenzae* show resistance to conventional antibiotic therapy.[1-3]

Ceclor is effective in the treatment of otitis media†, including that due to some ampicillin-resistant strains of *H. influenzae*.[4-9]

Ceclor has been shown to be clinically and bacteriologically effective in treating otitis media due to susceptible organisms.[10]

Ceclor is available in two pleasant-tasting liquids.

Ceclor provides effective single-agent antibiotic therapy for otitis media.

Note: Ceclor is contraindicated in patients with known allergy to the cephalosporins and should be given cautiously to penicillin-allergic patients.

†Due to susceptible strains of *Streptococcus pneumoniae*, *H. influenzae*, staphylococci, and *S. pyogenes*.

125-mg/5-ml and 250-mg/5-ml oral suspensions

Ceclor®

cefaclor

should be recognized that a positive Coombs test may be due to the drug.

Ceclor ® (cefaclor, Lilly) should be administered with caution in the presence of markedly impaired renal function. Under such a condition, careful clinical observation and laboratory studies should be made because safe dosage may be lower than that usually recommended.

Usage in Pregnancy—Although no teratogenic or antifertility effects were seen in reproduction studies in mice and rats receiving up to 12 times the maximum human dose or in ferrets given three times the maximum human dose, the safety of this drug for use in human pregnancy has not been established. The benefits of the drug in pregnant women should be weighed against a possible risk to the fetus.

Usage in Infancy—Safety of this product for use in infants less than one month of age has not been established.

Adverse Reactions: In clinical studies in 1493 patients, adverse effects considered related to cefaclor therapy were uncommon and are listed below:

Gastrointestinal symptoms occurred in about 2.5 percent of patients and included diarrhea (1 in 70) and nausea and vomiting (1 in 90).

Hypersensitivity reactions were reported in about 1.5 percent of patients and included morbilliform eruptions (1 in 100). Pruritus, urticaria, and positive Coombs tests each occurred in less than 1 in 200 patients.

Other effects considered related to therapy included eosinophilia (1 in 50 patients) and genital pruritus or vaginitis (less than 1 in 100 patients).

Causal Relationship Uncertain—Transitory abnormalities in clinical laboratory test results have been reported. Although they were of uncertain etiology, they are listed below to serve as alerting information for the physician.

Hepatic—Slight elevations in SGOT, SGPT, or alkaline phosphatase values (1 in 40).

Hematopoietic—Transient fluctuations in leukocyte count, predominantly lymphocytosis occurring in infants and young children (1 in 40).

Renal—Slight elevations in BUN or serum creatinine (less than 1 in 500) or abnormal urinalysis (less than 1 in 200).

Review

The Prostaglandins

Peter M. Olley, MD, Flavio Coceani, MD

During the last decade, the prostaglandins have attracted considerable research activity and have become of clinical importance in several disease states. It is probable that further clinical applications will develop in the future and, therefore, a review of our current knowledge of these biologically active compounds is timely. The reader should appreciate that information about the biosynthesis and metabolism of the prostaglandins (PGs) and related substances is increasing so rapidly that even the results of experiments performed recently have to be constantly reevaluated. What may seem to be true today may no longer be valid tomorrow!

"Prostaglandin" was the named coined by von Euler[1] in 1935 for an active substance found in lipid extracts of sheep seminal vesicles that both stimulated smooth muscle to contract and caused hypotension when injected into animals. Not all the compounds to be discussed in this article share the prostanoic acid skeleton, which is the essential component of PG structure; however, for convenience the term PG will be used in this review to designate the whole family of compounds.

Concurrent with von Euler's studies were those of Goldblatt[2,3] in England who also investigated the smooth muscle stimulating activity of seminal fluid from several species. Priority in describing a PG activity belongs to Kurzrok and Lieb[4] when they observed strong uterine relaxations or contractions in response to vaginal instillation of fresh semen in humans.

Further PG research was stimulated when Bergstrom et al[5,6] successfully crystallized minute amounts of PGE_1 and $PGF_{1\alpha}$ and with other collaborators elucidated their structure and that of several additional PGs. The 1970s have brought further major advances to the understanding of the family of PGs that will be discussed in the next section.

STRUCTURE

The PGs are 20-carbon unsaturated fatty acids whose structure comprises a cyclopentane ring with two aliphatic side chains. Each PG is designated by a letter dependent on its cyclopentane substituents and by a subscript numeral indicating the number of carbon-to-carbon double bonds present in the side chains. The "F" series in which the 9-hydroxyl group can potentially have one of two stereochemical orientations are further designated as being α or β. The β variant does not occur naturally. The thromboxanes (TX) differ from the PGs in having an oxane ring structure but share similar side chains and nomenclature. Prostacyclin (PGI_2) is a 6, 9-enol ether whose precise structure was recently elucidated (Fig 1).[7]

Prostaglandins are biosynthesized from dihomo-γ-linolenic acid (eicosatrienoic acid) and arachidonic acid (eicosatetranoic acid)[8,9] both of which are derived from the essential dietary fatty acid, linoleic acid. Synthesis from dihomo-γ-linolenic acid results in the "1" series of PGs, arachidonic acid is the precursor of the "2" series, whereas the "3" series are biosynthesized from eicosapentanoic acid.

The polyunsaturated fatty acid precursors are incorporated into phospholipids and, thus, are an important component of cell membranes. Prostaglandins have been found in all mammalian tissues studied, the predominant precursor present being arachidonic acid. Prostaglandins are not stored preformed but are synthesized and released as required. Arachidonic acid is split from the cell membrane phospholipids by an enzyme, phospholipase A_2,[10,11] and once released may be transformed via one of three different pathways (Fig 2).

The initial step always involves a site-specific incorporation of oxygen by a lipoxygenase-catalyzed reaction. Pathway 1 is the "classical" cyclooxygenase pathway and yields TXA_2, PGI_2, and the primary PGs (PGE_2, PGD_2, $PGF_{2\alpha}$) via the endoperoxide intermediates, PGG_2 and PGH_2. Pathways 2 and 3 are recent additions to the so-called PG system and yield a host of hydroxy, hydroperoxy, and epoxy products. These products in-

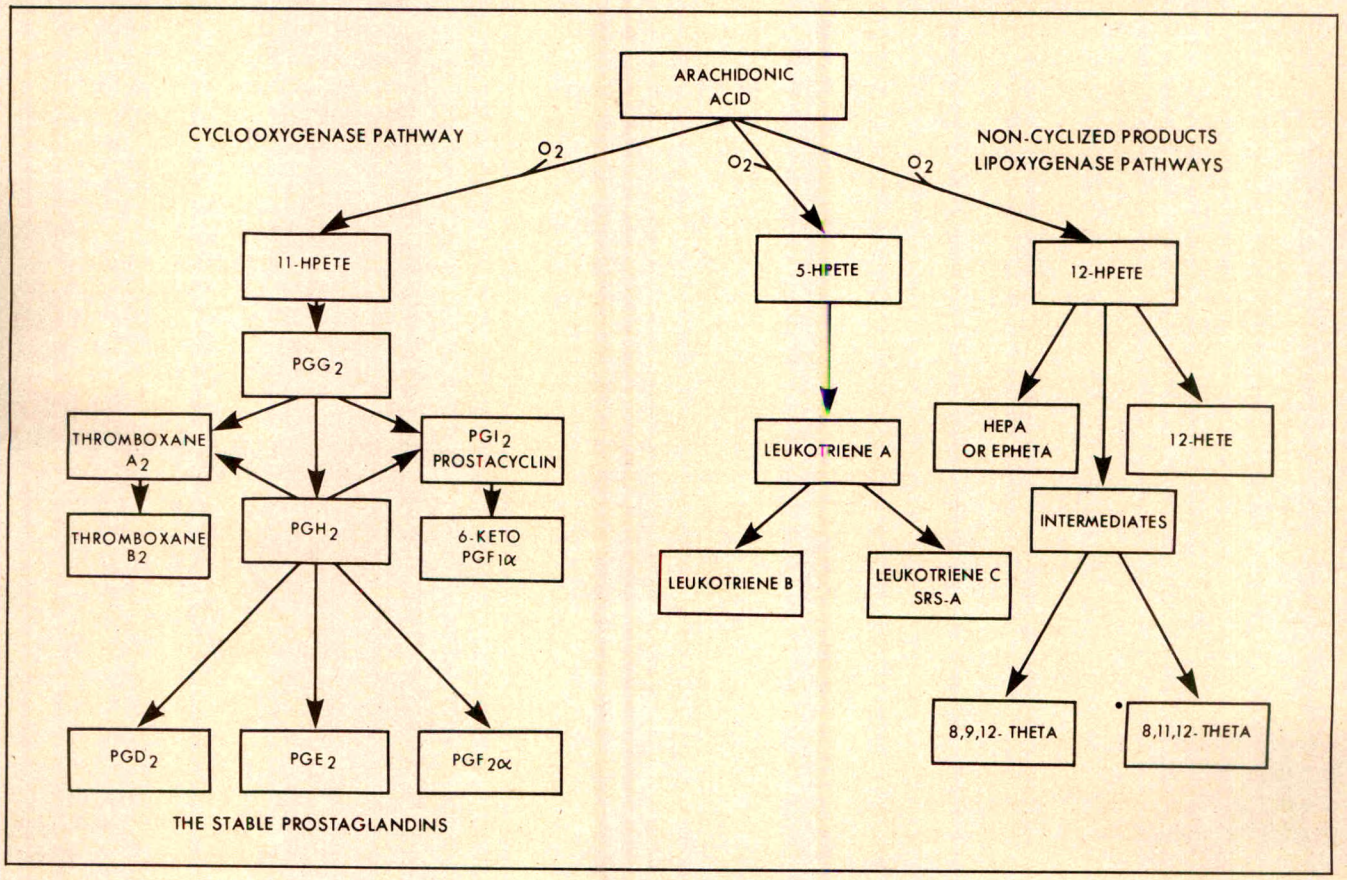
clude substances bearing three conjugated double bonds, the leukotrienes.[12,13] Although little is known of the occurrence and activity of noncyclized, oxygenated fatty acids in various tissues, the finding that leukotriene C is identical to slow-reacting substance A raises the possibility that pathways 2 and 3 may equal or exceed in importance the cyclooxygenase pathway. Because of these recent developments, the term "PG system" may not be appropriate to indicate the entire group of biologically active substances derived from arachidonic acid. Corey has proposed the alternative term of "eicosanoids."

The cyclooxygenase pathway has been much more extensively studied. Cyclooxygenase, located in the plasma membrane or endoplasmic reticulum, converts arachidonic acid by cyclization and inclusion of molecular oxygen[14,15] to unstable intermediates, the

Fig 2.—PG indicates prostaglandins; 11-HPETE, 11-hydroperoxy-5,8,12,14-e cosatetranoic acid; 5-HPETE, 5-hydroperoxy-6,8,11,14-eicosatetranoic acid; 12-HPETE, 12-hydroperoxy-5,8,10,14-eicosatetranoic acid; 12-HETE, 12-hydroxy-5,8,10,14-eicosatetranoic acid; HEPA, 10-hydroxy-11,12-epoxy-5,8,14-eicosatrienoic acid; 8,9,12-THETA, 8,9,12-trihydroxy-5,10,14-eicosatrienoic acid; 8,11,12-THETA, 8,11,12-trihydroxy-5,9,14-eicosatrienoic acid; and SRS-A, slow-reacting substance-A.



endoperoxides.[16,17] These intermediates have been designated PGG_2 and PGH_2. Prostaglandin G_2 is formed first and is rapidly converted to PGH_2. Both PGG_2 and PGH_2 are substrates for further transformations by several pathways. The biological half-life in aqueous solution of both these compounds is about five minutes at 37 °C. Transformation of PGH_2 to the stable primary PGs (PGD_2, PGE_2, and $PGF_{2\alpha}$) occurs either nonenzymatically or by isomerase or reductase enzymes that occur widely in mammalian tissues; their distribution is uneven and concentrations of a specific enzyme may vary according to the tissue under study.

In platelets, the lungs, the spleen, and probably in other tissues, PGG_2 and PGH_2 may be transformed to the non-PG metabolite TXA_2 that has a half-life of about 30 s and is further metabolized to the inactive TXB_2. Thromboxane A_2 aggregates platelets, constricts arteries, and accounts for most of the biological activity of so-called rabbit aorta contracting substance.[18]

The endoperoxides may also be enzymatically transformed to the unstable PGI_2 that prevents platelet aggregation and is a vasodilator.[19] At 37 °C and a physiological pH value, PGI_2 has a half-life of two to three minutes that can, however, be prolonged in an alkaline medium. The PGI_2 spontaneously hydrolyses to the much more stable 6-keto-$PGF_{1\alpha}$ that occurs in several tissues, including fetal and adult vessels, heart, lungs, and uterus.

The PGs and TXs are synthesized and released in response to cell stimulation. In a given tissue, the amount and type of PG produced depends on the nature and availability of substrate, on the spectrum of synthesizing enzymes present, and on the presence of cofactors. The pattern of PG production may be unique to a given tissue and may be altered by extrinsic stimuli, such as catecholamines, kinins, trauma, and hypoxia. In tissues where different PGs have opposing actions, this ability to alter the amount of individual PGs produced provides a mechanism for controlling physiological processes.

Further potential for modifying cell activity rests in the presence of enzymes capable of transforming one active PG to another.[8] The 9-keto-reductase that converts PGE_2 to $PGF_{2\alpha}$ has been identified in several tissues from different species, including human kidney and blood vessels. Prostaglandin D_2 can be converted to $PGF_{2\alpha}$ in sheep and humans. Recent work suggests that in the liver 6-keto-$PGF_{1\alpha}$, the relatively inactive metabolite of PGI_2, can be enzymatically converted to the biologically active 6-keto-PGE_1.[20]

Degrading enzymes capable of metabolizing $PGF_{2\alpha}$ and PGE_2 to less active compounds occur in many tissues. The lung, spleen, and kidney contain 15-hydroxyprostaglandin dehydrogenase that converts $PGF_{2\alpha}$ and PGE_2 to the much less active 15-keto derivatives, while a PG-Δ13-reductase is present in most organs.

E- and F-type PGs have an extremely short half-life in the circulation and are up to 95% inactivated during a single pass through the lungs.[21] Fetal and newborn sheep lungs also inactivate PGE_1 to a similar degree.[22] Pulmonary metabolites of PG undergo β-oxidation in the liver and kidney to 18- and 16-carbon compounds and the resulting inactive metabolites are excreted in the urine. ω-Oxidation also occurs in the liver.

INHIBITORS OF PG SYNTHESIS

Conversion of arachidonic acid to the endoperoxides by cyclooxygenase is inhibited by nonsteroidal anti-inflammatory drugs, such as aspirin and indomethacin. This action occurs in numerous species and in conditions varying from microsomal preparations of the enzyme through to whole organs or organisms. Measurements in man suggest that the usual therapeutic doses are sufficient to inhibit PG biosynthesis. Cyclooxygenase inhibition interferes not only with the formation of the stable PGs but also with that of the endoperoxides, TXA_2, and PGI_2; however, the lipoxygenase pathways are not blocked and production of their metabolites could be enhanced.

Moncada and Vane[23] have proposed that it is this enzyme inhibition that underlies the therapeutic actions of aspirin-like drugs in reducing fever, pain, and inflammation and the side effects of these agents are caused by concomitant suppression of PG biosynthesis required for normal cell activity. This attractive theory has been challenged by Smith[24] mainly on the grounds that salicyclic acid, as potent an anti-inflammatory agent as aspirin in vivo, has no inhibitory effect on cyclooxygenase in vitro. Furthermore, enzymes from differing tissues have varying sensitivities to aspirin-like drugs. The paradox of salicyclic acid remains to be resolved but the weight of evidence is in favor of the hypothesis proposed by Moncada and Vane.

Several more selective inhibitors are now under study. Imidazole and benzydamine hydrochloride interfere with thromboxane synthesis, whereas tranylcypromine and 15-hydroperoxyarachidonic acid inhibit PGI_2 production. (Rajtar and deGaetano[25] recently reported lack of selective inhibitory activity of tranylcypromine on vascular PGI_2 synthesis in the rat.) Such selective inhibitors may also divert arachidonic acid metabolism along unblocked pathways, thus increasing the formation of other metabolites.

Steroids and quinacrine hydrochloride also interfere with PG formation by preventing the release of substrate from membrane phospholipid by phospholipase A_2[26] and perhaps by reducing transport of the nonesterified arachidonic acid to the cyclooxygenase.

PHYSIOLOGICAL FUNCTION OF PGs

Despite the enormous volume of research in the last decade the role and importance of PGs in cell physiology remains unclear and seemingly attractive hypotheses based on the known actions of the stable PGs are now being reassessed to take into account the TX and PGI_2 pathways. The cyclic nucleotides and calcium ion are clearly universal and interrelated second messengers in the activation of particular cell types responding to specific extracellular stimuli. The Yin-Yang hypothesis postulates that the intracellular ratio of cyclic adenosine 3′,5′-monophosphate (cAMP) to cyclic

guanosine 3′,5′-monophosphate (cGMP) controls cells function. For example, in vascular smooth muscle cAMP causes relaxation, whereas cGMP produces contraction.[27,28]

E-type PGs elevate AMP concentrations in several tissues by stimulating adenylcyclase, whereas in contrast $PGF_{2\alpha}$ stimulates cGMP formation in a variety of tissues. More recently, the TXs and PGI_2 have been shown to affect cellular cyclic nucleotide concentrations.[29,30] Even though a simple relationship between the stable PGs and intracellular cAMP and cGMP levels now seems unlikely, further studies of the role of the expanded PG family in modifying intracellular events seems more than justified.

The PGs have also been implicated as modulators of sympathetic neurotransmission.[31-33] Hedqvist[34] has reviewed the evidence showing that exogenous PGE compounds may affect sympathetic neurotransmission by acting at both prejunctional and postjunctional levels. At the postjunctional level, their action may be inhibitory or stimulatory, depending on the tissue studied and/or the dose of PG used. An inhibitory presynaptic action has been shown in spleen, heart, and vas deferens. Nerve stimulation increases both formation and release of PGE compounds in many sympathetically innervated tissues. Based on these findings, Hedqvist has proposed that endogenous PGs of the E series modulate sympathetic neurotransmission by a feedback mechanism. This proposal generated numerous additional studies to obtain evidence in support of, or against, Hedqvist's hypothesis (reviewed by Westfall[33]). In summary, it seems that although the predominant effect of E-type PGs is inhibition of norepinephrine release, this action is not universal and there are examples of tissues in which there is no effect or in which responsiveness to nerve stimulation is enhanced.

Prostaglandin $F_{2\alpha}$ seems to have no effect or to enhance the effector cell response to nerve stimulation and exogenous norepinephrine but at present seems to be much less important than E_2 in the control of sympathetic neurotransmission.[33] Ultimately, the PGs may influence cell activity by their action on calcium transport both within the cell where TXA_2 may convey calcium unidirectionally from the sequestered sites in the dense tubular system into the cytoplasm and across the cell membrane.[35]

Arachidonic acid metabolites with their rapid biosynthesis are equally rapid inactivation coupled with their diverse actions seem ideally endowed to act as modulators of intracellular events and perhaps as messengers between adjacent cells. They seem less fitted to a role as circulating hormones, although they could be carried in the blood bound to protein and then released to act on a distant target organ or cell. While their role in diverse organs and tissue remains under active investigation, a unifying concept awaits elucidation.

ASSAY METHODS

Because PGs are not stored in tissues but are rapidly biosynthesized, degraded measurements of tissue concentrations must be interpreted with caution. Three types of quantitative assays for the PGs are in current use.

Bioassay can be performed in vitro or in vivo. The in vitro "cascade" uses several different organs superfused consecutively by the same sample.[36] The specificity of each organ can be increased by pretreatment with specific antagonists against other biologically active materials and by prior purification of the sample. The advantages of bioassay are that it is the only possible method for screening labile unknowns and is reasonably sensitive (can detect < 1 ng of pure active compound). On the other hand, it cannot be used to quantitate biologically inactive metabolites; it has a low-sample capacity and even with pretreatment the specificity may be questionable. The results may be affected by metabolism of the test compounds by one or more of the organs, a danger that can be partially overcome by changing the order of the organs.

Radioimmunoassay (RIA)[37-39] is relatively cheap and sensitive (detects < 50 pg) and with proper precautions can be fairly specific. The technique is relatively simple and has a large-sample capacity. One must be aware of interpretational errors from cross-reactivity. Granstrom[38] has warned against the "kit mentality" in the use of RIA.

Gas chromatography-mass spectrometry (GC-MS) is the reference method. Introduced by Samuelsson and associates for PGE_1,[40] it has now been extended to a large number of related compounds.[41] Highly specific, GC-MS permits simultaneous analysis of several compounds with a high sensitivity (50 to 250 pg). It has the disadvantages of being expensive and time consuming. Sample size is low and it requires elaborate purification procedures.

Although it is possible to measure various PG concentrations in plasma, serum, or urine, one must be aware of the great fluctuations in concentrations that occur. Hillier has discussed the sources of error in such measurements.[42]

Levels of $PGF_{2\alpha}$ are elevated in sheep uterine venous plasma at parturition,[43] while the concentration of PGE in fetal plasma is raised shortly before delivery as are those in amniotic fluid.[44] The concentrations of 6-keto-$PGF_{1\alpha}$ are also elevated in maternal and fetal plasma and in amniotic fluid during late pregnancy and parturition in sheep.[45] These findings suggest a role for the PGs in the control of fetal and placental hemodynamics and of parturition. Mitchell et al[46,47] studied plasma PG levels during early neonatal life in term infants and in preterm infants before and after treatment for patent ductus arteriosus. Prematurity per se was not associated with substantially different levels of PGE, PGF, or PGF metabolite but in nine premature infants with patent ductus arteriosus and congestive heart failure levels were significantly higher ($P < .01$) and did not decrease after surgical ligation of the ductus arteriosus. Hyaline membrane disease is also associated with the noticeable elevation of plasma PGF level, which is a vasoconstrictor and may contribute to the circulatory problem in these infants.[48] Levels of PGE in cord blood are substantially higher than those in adults, but by 48

to 72 hours decrease to concentrations substantially below those in adults. Thereafter, they increase with age, but remain less than adult levels.[49]

PGs, INFLAMMATION, AND FEVER

Inflammation is associated with the local release of a number of vasoactive substances, including histamine, 5-hydroxytryptamine (5-HT), slow-reacting substance of anaphylaxis, bradykinin, TXA_2, E and F PGs, lysosomal enzymes, and chemotaxins. Anti-inflammatory agents have little effect on histamine, 5-HT, and bradykinin actions, but by antagonizing PG biosynthesis, they prevent inflammatory responses mediated by arachidonic acid metabolites.

The nature of the inflammatory response depends on tissue sensitivity and on the spectrum and sequence of mediator released. In anaphylactic shock, multiple mediators are released simultaneously,[50] whereas subcutaneous carrageenin in the rat invokes a sequential release of histamine, bradykinin, and then PGs.[51] The metabolite of PGI_2, 6-keto-$PGF_{1\alpha}$, has been found in chronic granulomas.[52] One of the metabolites of the lipoxygenase pathway is highly chemotactic.[53]

The E-type PGs (also F-type and PGI_2 to a lesser extent) cause erythema from pooling in relaxed vessels and edema from increased vascular permeability in postcapillary and collecting venules. Low concentrations of PGE_1 subdermally cause hyperalgesia, whereas higher doses cause long-lasting pain. Prostaglandins seem to sensitize sensory nerves to chemical stimulation by other substances and to exacerbate histamine-induced pruritus. Aspirin and related substances, by preventing PG generation, relieve the symptoms of inflammation.[54] While Kuehl et al[55] have proposed that the endoperoxides, rather than the stable PGs, occupy the central role in the mechanism of inflammation, this does not nullify the current concepts of the action of aspirin.

The E-type PGs are the most powerful pyretic known and act in a dose-dependent fashion when injected into the cerebral ventricles or the anterior hypothalamus[56,57]; the onset of fever is almost immediate and lasts several hours. Arachidonic acid also induces fever, but with some latency, this effect is blocked by aspirin. Prostaglandin E is generated during spontaneous fever and concentrations in the CSF rise. Patients given PGE_2 or $PGF_{2\alpha}$ to induce abortion[58] or to maintain patency of the ductus arteriosus frequently become febrile.[59] Aspirin and related drugs inhibit the generation of PGs in the CNS during fever and prevent pyrogen-induced fever.[60]

One may conclude that it is highly probable that metabolites of arachidonic acid are intimately involved in the pathogenesis of inflammation, pain, and fever and that the beneficial effect of aspirin and related drugs on these symptoms is due to cyclooxygenase inhibition.

PGs and Ductus Arteriosus

The ductus arteriosus contains a cyclooxygenase[61-63] and possibly lipoxygenase[64] as well. Prostaglandin I_2 seems to be the major product as in other vessels. Cyclooxygenase inhibition with indomethacin or ibuprofen constricts the fetal ductus arteriosus in vitro and in vivo.[65] This action is more noticeable in premature animals and is fully reversed by treatment with PGE_1 or PGE_2. On the basis of this evidence, patency of the fetal ductus arteriosus is now regarded as an active state sustained by a continuous intramural production of PG. Prostaglandin E_2 is the prime candidate for this role.[65] However, PGI_2 may acquire a more central function should future investigations demonstrate the presence in ductal tissue of an enzyme system able to convert 6-keto-$PGF_{1\alpha}$ to 6-keto-PGE_1. This latter compound is a potent antithrombotic and ductus-relaxing agent.[66]

The postnatal increase in blood oxygen content initiates closure of the ductus arteriosus, although it is not clear whether this is a direct action or involves some vasoactive mediator. Both $PGF_{2\alpha}$[67] and TXA_2[68] have been proposed for this role, but the balance of evidence is against this possibility. An alternative possibility is that oxygen-induced contraction results from a withdrawal of the tonic-relaxing influence of endogenous PGs.

Clinical use of these experimental data has been made in newborn infants with heart disease and in premature babies with a patent ductus arteriosus and significant left-to-right shunting. A continuous infusion of PGE_1 (0.05 to 0.1 μg/kg/min) given either intraarterially or intravenously maintains ductal patency in infants with ductus-dependent cardiac malformations, allowing time for reversal of hypoxia, correction of metabolic acidosis, and arrangement of semi-elective surgical intervention.[69]

In contrast, indomethacin (0.3 to 0.6 mg/kg/24 hr) has been used successfully to close the ductus arteriosus in premature infants. Reported success rates have varied and the factors determining responsiveness remain obscure.[70-72] Actual age at time of therapy,[73] concomitant drug therapy,[74] or circulating PG levels may all be important. Failure of drug absorption does not seem to be a factor.[75] The final place for indomethacin, or, in the future, more specific synthesis blockers, in the problem ductus of the premature is still under evaluation and must be compared with the excellent results now being achieved by the surgeons.

PGs AND LUNGS

The products of arachidonic acid metabolism within the lungs include PGD_2, PGE_2, $PGF_{2\alpha}$, TXB_2, and 6-keto-$PGF_{1\alpha}$, the latter implying active synthesis of PGI_2. The physiologic importance of these compounds to both normal bronchomotor tone and to the control of the pulmonary circulation is currently under active investigation.[76,77]

Exogenous PGE_1 is a pulmonary vasodilator in both neonatal[78] and adult animals, whereas $PGF_{2\alpha}$ is a constrictor. Prostaglandin D_2 has a constrictor action, whereas PGE_2 has been found to be both a constrictor[79] and a dilator.[78] Kadowitz et al[79] have attempted to explain the somewhat anomalous action of PGE_2 on the basis of conversion to $PGF_{2\alpha}$. Prostaglandin I_2 has been reported to be a dilator in the cat.[80] In conscious newborn lambs, PGD_2 and $PGF_{2\alpha}$ are direct pulmonary vasoconstrictors, whereas PGE_1, PGE_2, and PGI_2 are direct vasodila-

tors. During hypoxia, the PGE_1 and PGI_2 effects are enhanced while the constrictor action of PGD_2 and $PGF_{2\alpha}$ is diminished. Hypoxia also lowers the threshold for PGI_2-induced dilation.[81]

Although the E-type PGs and PGI_2 are both local dilators, they differ in that the systemic dilatory effects of the E-type agents exceed their pulmonary effects, whereas under hypoxia the opposite occurs with PGI_2. Thus, PGs can act locally on pulmonary vascular smooth muscle in vivo and their action is influenced by the level of oxygenation or baseline vascular tone.[81]

A bolus injection of indomethacin induces acute pulmonary vasoconstriction. Chronic indomethacin therapy neither alters baseline pulmonary tone nor the pulmonary vascular responses to hypoxia, acetylcholine, bradykinin, or histamine. However, pretreatment with indomethacin does abolish the pulmonary effects of a further intravenous dose of the drug.[82] These results suggest that although the PGs may have a role in the control of pulmonary vascular tone, they are not essential to that control.

Because of its apparently selective pulmonary vasodilating effects, PGI_2 is of potential value in the therapy of conditions in which pulmonary vasoconstriction plays a role. A continuous infusion of PGI_2 was successful in lowering pulmonary resistance in a newborn with persistent fetal circulation syndrome.[83]

The effects of the PGs on pulmonary vessels are paralleled by their effects on bronchomotor tone. Prostaglandin $F_{2\alpha}$ is a potent bronchoconstrictor, especially in asthmatics. Prostaglandin E_1 and E_2 are bronchodilators, their action being unaffected by α- or β-adrenoreceptor blockade. Aspirin and indomethacin decrease the intrinsic tone of guinea pig tracheal rings, whereas TXA_2 and the endoperoxides are ten times more active than $PGF_{2\alpha}$ in causing contraction in the same experimental model.[77]

Aspirin-induced asthma may result from inhibition of endogenous PGE_2 production; with the loss of its bronchodilator effect, the bronchi constrict in response to histamine and other mediators.[84] Unfortunately, the therapeutic use of aerosolized E-type PGs in asthmatic subjects has proved disappointing. Not only is the response unpredictable but they cause consistent irritation of the upper airways. Possibly PGE_1 or PGE_2 analogues may prove to be more useful.

PGs IN REPRODUCTION

Arachidonic acid is relatively abundant in reproductive tissues, including umbilical cord, fetal membranes, placenta, myometrium, decidua, amniotic fluid, and maternal and fetal plasma.[85] Biosynthesis of PGE_2 has been demonstrated in umbilical cord, fetal membranes, decidua, and myometrium. Prostaglandin metabolism occurs in the chorion and placenta. Exogenous PGs contract the human uterus by a direct action on myometrial cells, PGE_2 being some ten times more potent than $PGF_{2\alpha}$. Prostaglandins are luteolytic in many subprimate species but not in humans. Prostaglandin concentrations in blood and amniotic fluid are raised during labor in many species, including humans, and decrease abruptly when labor is over.[86]

Prostaglandin $F_{2\alpha}$ effectively terminates pregnancy at all stages of gestation whether given vaginally, extraamniotically or intraamniotically, or intramuscularly, and has been used clinically to induce labor at term and second-trimester abortions. When used to induce term labor, especially in nulliparous women, there is an increased risk of hypertonus and fetal bradycardia, than during spontaneous labor or surgical induction.[87] Prostaglandin E_2 and its 15-methyl analogue given orally are also under evaluation for labor induction.

In pregnant women and monkeys, aspirin and related compounds prolong gestation and delay parturition[88,89] and oral indomethacin has been used to treat women in premature labor.[90-92] Karim[91] has reviewed the possible hazards to the fetus from administration of PG synthetase inhibitors to the mother that may include teratogenicity, increased incidence of stillbirth; circulatory effects, such as intrauterine closure of the ductus arteriosus and fetal hemorrhage.[91] Pulmonary hypertension, premature closure of the ductus arteriosus, and tricuspid insufficiency have been reported in the infants of mothers who received indomethacin.[93,94] Carefully conducted clinical trials in a few centers are clearly necessary to assess the true risks to the fetus of this approach to premature labor.

PGs, PLATELETS, AND VASCULAR INTEGRITY

Much of the basic research on the PG system has been done on platelets and on the interactions between platelets and vessel walls. It now seems that PGI_2 and TXA_2 are more important to these interactions than are the stable PGs. Prostaglandin E_1, but paradoxically not PGE_2, inhibits platelet aggregation induced by adenosine diphosphate, collagen, or adrenaline.[95] However, little PGE_1 is likely to be formed in platelets that contain hardly any of its precursor, dihomo-γ-linolenic acid. When tested, the PG endoperoxides were found to be strongly proaggregatory and this action was subsequently found to be due to transformation to TXA_2.[96] Thromboxane A_2 also proved to be a potent arterial vasoconstrictor. In contrast, PGI_2, the major arachidonic acid metabolite in vessel walls, has a strong antiaggregatory action on platelets as well as being a powerful vasodilator. Generation of PGI_2 within the vessel wall and from endoperoxides released by platelets may well be the physiologic mechanism that protects the damaged vessel wall from deposition of platelet aggregates. The opposing actions of TXA_2 and PGI_2 suggests a homeostatic mechanism that preserves vascular integrity.[97]

Prostacyclin can be released from the lung into arterial blood. Moncada and Vane[97] have suggested that circulating PGI_2 may have a continuing role in preventing platelet aggregation by constantly activating platelet adenylate cyclase. Furthermore, PGI_2 also disaggregates platelet clumps as well as discouraging their formation, this could be of special protective value in the pulmonary microcirculation in which platelets are trapped.

New knowledge about arachidonic acid metabolites and platelet aggrega-

tion has led to a better understanding of the mode of action of several antithrombotic agents. Aspirin irreversibly inactivates platelet cyclooxygenase by acetylation of the active sites, thereby preventing TXA_2 formation,[98] while dipyridamole potentiates the action of PGI_2 on platelets by inhibition of phosphodiesterase.[99] Burch et al[100] have shown that cyclooxygenase in human aorta and coronary artery microsomes is some 250 times less sensitive to aspirin than the enzyme in intact platelets and some 60 times less sensitive than the enzyme measured in a platelet microsomal fraction. On the basis of their in vitro data, they predict that small oral doses of aspirin are sufficient to inhibit platelet TX production, while having little action on aorta or coronary artery PGI_2 production. If confirmed, this finding is of great importance to the various trials of antithrombotic agents currently in progress.

How important are arachidonic acid metabolites to normal hemostasis? Malmsten et al[101] described a patient with a hemostatic defect from platelet cyclooxygenase deficiency. Platelets from rats fed dihomo-γ-linolenic acid showed decreased aggregation in response to collagen or epinephrine.[102] However, against the PGs having a central role in hemostasis is the finding that thrombin induces complete platelet aggregation and release, in both aspirin-treated platelets and in platelets from the patient with cyclooxygenase deficiency. Majerus[103] has suggested that aspirin induces a mild defect in platelet function that increases the threshold for platelet aggregation and release reaction.

However, this may be of clinical importance. Platelet aggregation in premature infants given indomethacin to induce ductal closure was grossly abnormal for two to four days after administration and in one of four infants studied by Friedman et al,[104] gastrointestinal bleeding and transient renal dysfunction developed.

The relationship between diet and the incidence of myocardial infarction remains the subject of intensive research. Eskimos have a low incidence of myocardial infarction and an increased tendency to bleed and this could be related to the high proportion of eicosapentanoic acid in their diet that is mainly derived from marine animals. Eicosapentanoic acid is the precursor of the three series of PGs and can be transformed to an antiaggregatory agent, probably PGI_3, whereas TXA_3, although formed, is nonaggregatory. Thus, a diet high in eicosapentanoic acid and relatively low in linoleic and arachidonic acid may help to protect against intravascular thrombosis. Dietary linoleic acid is converted to arachidonic acid in the body and is essential for the formation of membrane phospholipids. Further studies of the influence of these precursors on the balance between platelet aggregation and nonaggregation are clearly of great importance.

OTHER CLINICAL POSSIBILITIES

Essential fatty acid deficiency has been noted in cystic fibrosis,[105] and PG synthesis may be reduced either secondary to diminished availability of linoleic acid[106] or to impaired oxidation of fatty acids.[107] Chase and Dupont[108] found that the production of $PGF_{2\alpha}$ from linoleic acid is higher in children with cystic fibrosis than in controls, even though the children with cystic fibrosis had lower plasma levels of linoleic acid. Prostaglandin $F_{2\alpha}$ is both a pulmonary vasoconstrictor and a bronchoconstrictor and its overproduction over a long period of time could be important in the pathophysiology of cystic fibrosis. In a trial of intravenously administered soya bean emulsion (intralipid) in seven children with cystic fibrosis treated for a year or more, Elliott[106] observed remarkably better health than in others with cystic fibrosis not treated with intralipid. These results require confirmation in properly randomized clinical trials.

Increased PG synthesis has been found in children with diabetes mellitus who had elevated blood levels of PGE_2, $PGF_{2\alpha}$, and linoleic acid[109] and may be related to the vascular complications inflicting diabetics.

Overproduction of E-type PGs has been proposed to explain Bartter's syndrome, which is characterized by hypokalemic alkalosis, increased plasma renin activity and aldosterone, juxtaglomerular cell hyperplasia, low or normal blood pressure, and decreased sensitivity to angiotensin.[110] Based on this hypothesis, PG synthetase inhibitors have been used to treat Bartter's syndrome in both adults and children with successful reversal of clinical and biochemical abnormalities.[111,112]

CONCLUSION

This article is of necessity incomplete. Reviews of the importance of the PGs to the nervous system[60] and in renal physiology[113] have been published recently. The progressive unfolding of the PG story, doubtless still far from complete, enforces a constant reappraisal of concepts, theories, and apparently established facts. Indeed, even the name "prostaglandins" is in jeopardy and may be superseded by the more embrassive term "eicosanoids."

Although the physiologic role of the arachidonic acid metabolites remains uncertain, a number of clinical applications have emerged. The next decade will undoubtedly bring further exciting developments in this field.

Indications: *ATTENUVAX® (Measles Virus Vaccine, Live, Attenuated, MSD)*—Active immunization against measles (rubeola) in children 15 months of age or older.
BIAVAX®II (Rubella and Mumps Virus Vaccine, Live, MSD)—Simultaneous immunization against rubella and mumps in children 15 months of age to puberty. May be given as early as 12 months if that offers greater convenience in scheduling.
MERUVAX®II (Rubella Virus Vaccine, Live, MSD)—Immunization against rubella (German measles) in children 15 months of age to puberty. May be given as early as 12 months if that offers greater convenience in scheduling. May be useful for adolescent and adult males to prevent or control rubella outbreaks in circumscribed population groups. In postpubertal females vaccination must not be undertaken unless the woman is not pregnant, is susceptible to rubella (as shown by Hemagglutination Inhibition test), agrees not to become pregnant for next three months (also in immediate postpartum period), and is informed of frequent occurrence of self-limited arthralgia and possible arthritis beginning two to four weeks after vaccination.
M-M-R®II (Measles, Mumps and Rubella Virus Vaccine, Live, MSD)—Simultaneous immunization against measles, mumps, and rubella in children 15 months of age to puberty.
M-R-VAX®II (Measles and Rubella Virus Vaccine, Live, MSD)—Simultaneous immunization against measles (rubeola) and rubella (German measles) in children 15 months of age to puberty.
MUMPSVAX® (Mumps Virus Vaccine, Live, MSD)—Immunization against mumps for children 15 months of age or older and adults. May be given as early as 12 months if that offers greater convenience in scheduling.

Contraindications: Pregnancy or the possibility of pregnancy within three months following vaccination (see special considerations for ATTENUVAX below); hypersensitivity to neomycin; any febrile respiratory illness or other active infection; for measles-containing vaccines, active untreated tuberculosis; therapy with ACTH, corticosteroids (except as replacement therapy, e.g., for Addison's disease), irradiation, alkylating agents, or antimetabolites; blood dyscrasias, leukemia, lymphomas of any type, or other malignant neoplasms affecting the bone marrow or lymphatic systems; primary immunodeficiency states, including cellular immune deficiencies, hypogammaglobulinemic and dysgammaglobulinemic states.

Hypersensitivity to Eggs, Chicken, or Chicken Feathers: For measles- and/or mumps-containing vaccines, in patients hypersensitive to eggs, chicken, or chicken feathers, weigh benefits of immunization against potential risks of hypersensitivity reactions.

Pregnancy: *ATTENUVAX*—The effects of ATTENUVAX on fetal development are unknown at this time. Live attenuated measles virus vaccine should not be given to persons known to be pregnant; furthermore, pregnancy should be avoided for three months following vaccination. Reports have indicated that natural measles during pregnancy enhances fetal risk. Increased rates of spontaneous abortion, stillbirth, congenital defects, and prematurity have been observed subsequent to natural measles during pregnancy. There are no adequate studies of the attenuated (vaccine) strain of measles virus in pregnancy. However, it would be prudent to assume that the vaccine strain of virus is also capable of inducing adverse fetal effects for up to three months following vaccination.
Vaccine administration to postpubertal females entails a potential for inadvertent immunization during pregnancy. Theoretical risks involved should be weighed against the risks that measles poses to the unimmunized adolescent or adult. Advisory committees reviewing this matter have recommended vaccination of postpubertal females who are presumed to be susceptible to measles and not known to be pregnant. If a measles exposure occurs during pregnancy, one should consider the possibility of providing temporary passive immunity through the administration of immune serum globulin (human).

Precautions: Administer subcutaneously; *do not give intravenously.* Epinephrine should be available for immediate use should an anaphylactoid reaction occur. Should not be given less than one month before or after immunization with other *live* virus vaccines, with the exception that ATTENUVAX, MUMPSVAX, and/or MERUVAX II may be administered simultaneously. BIAVAX II may be administered simultaneously with ATTENUVAX. Monovalent or trivalent poliovirus vaccine, live, oral, may be administered simultaneously with ATTENUVAX and/or MUMPSVAX. Vaccinations should be deferred for at least three months following blood or plasma transfusions or administration of more than 0.02 ml human immune serum globulin per pound of body weight. However, rubella vaccine may be given prior to discharge to susceptible postpartum patients who received blood products, provided that a repeat HI titer is drawn six to eight weeks after vaccination to insure seroconversion; similarly, although rubella vaccine may be given in the immediate postpartum period to those nonimmune women who have received anti-Rh_0 (D) immune globulin (human) without interfering with vaccine effectiveness, a follow-up postvaccination HI titer should also be determined.
Attenuated measles, mumps, and rubella virus vaccines, live, given separately, may result in a temporary depression of tuberculin skin sensitivity; therefore, if a tuberculin test is to be done, it should be administered before or simultaneously with any of these virus vaccines. Vaccination may not result in seroconversion in 100 percent of susceptible subjects.
Measles-Containing Vaccines—Due caution should be employed in children with a history of febrile convulsions, cerebral injury, or any other condition in which stress due to fever should be avoided. The physician should be alert to the temperature elevation which may occur 5 to 12 days after vaccination. The occurrence of thrombocytopenia and purpura has been extremely rare.
Rubella-Containing Vaccines—Excretion of live attenuated rubella virus from the nose and throat has occurred in the majority of susceptible individuals 7 to 28 days after vaccination. There is no confirmed evidence to indicate that such virus is transmitted to susceptible persons who are in contact with vaccinated individuals. Consequently, transmission, while accepted as a theoretical possibility, is not regarded as a significant risk.

Adverse Reactions: To date, clinical evaluation of the combination vaccines has revealed those adverse reactions expected to follow administration of the monovalent vaccines given separately.
Measles-Containing Vaccines—Occasionally, moderate fever (101–102.9 F); less commonly, high fever (above 103 F); rarely, febrile convulsions. Infrequently, rash, usually minimal without generalized distribution. Reactions at injection site. Local reactions characterized by marked swelling, redness, and vesiculation at the injection site of attenuated live measles virus vaccines have occurred in children who previously received killed measles vaccine; the combination vaccines were not given under this condition in clinical trials.
Experience from more than 80 million doses of all live measles vaccines given in the U.S. through 1975 indicates that significant central nervous system reactions such as encephalitis and encephalopathy, occurring within 30 days after vaccination, have been temporally associated with measles vaccine approximately once for every million doses. In no case has it been shown that reactions were actually caused by vaccine. The Center for Disease Control has pointed out that "a certain number of cases of encephalitis may be expected to occur in a large childhood population in a defined period of time even when no vaccines are administered." However, the data suggest the possibility that some of these cases may have been caused by measles vaccines. The risk of such serious neurological disorders following live measles virus vaccine administration remains far less than that for encephalitis and encephalopathy with natural measles (one per thousand reported cases). There have been reports of subacute sclerosing panencephalitis (SSPE) in children who did not have a history of natural measles but did receive measles vaccine. Some of these cases may have resulted from unrecognized measles in the first year of life or possibly from the measles vaccination. Based on estimated nationwide measles vaccine distribution, the association of SSPE cases to measles vaccination is about one case per million vaccine doses distributed, far less than the 5 to 10 cases of SSPE per million cases of natural measles.
Rubella-Containing Vaccines—Adverse reactions include malaise, sore throat, headache, fever, and rash; mild local reactions such as erythema, local pain, induration, tenderness, and regional lymphadenopathy; thrombocytopenia and purpura; allergic reactions such as urticaria; and arthritis, arthralgia that is infrequently associated with signs of inflammation, and polyneuritis.
Moderate fever (101–102.9 F) occurs occasionally, and high fever (103 F) occurs less commonly. Rash occurs infrequently and is usually minimal without generalized distribution. Encephalitis and other nervous system reactions have occurred very rarely.
Transient arthritis, arthralgia, and polyneuritis vary in frequency and severity with age and sex; being greatest in adult females and least in prepubertal children. In children, joint reactions are rare and of brief duration if they do occur. In women, incidence rates for arthritis and arthralgia are generally higher than those seen in children (children: 0–3 percent; women: 12–20 percent), and the reactions tend to be more marked and of longer duration. Rarely, symptoms may persist for a matter of months. In adolescent girls, the reactions appear to be intermediate in incidence between those seen in children and in adult women. Even in older women (35–45 years), these reactions are generally well tolerated and rarely interfere with normal activities.
Mumps-Containing Vaccines—Parotitis and orchitis. Rarely, purpura and allergic reactions such as urticaria. Very rarely, encephalitis and other nervous system reactions. With the monovalent mumps vaccine, mild fever occurs occasionally, and fever above 103 F is uncommon.

Shipment, Storage, and Reconstitution: During shipment, to insure that there is no loss of potency, the vaccine must be maintained at a temperature of 10 C (50 F) or less. Before reconstitution, store vaccines at 2–8 C (35.6–46.4 F) and *protect from light.* Use only diluent supplied to reconstitute vaccines. If not used immediately, store reconstituted vaccines in a dark place at 2–8 C (35.6–46.4 F), and discard if not used within eight hours. Use a separate sterile syringe and needle for each individual patient to prevent transmission of infectious agents from one person to another.
Color: The color of the vaccine when reconstituted is yellow. ATTENUVAX is acceptable for use only if clear.

How Supplied: *ATTENUVAX® (Measles Virus Vaccine, Live, Attenuated, MSD)*—Single-dose vials of lyophilized vaccine, containing when reconstituted not less than the equivalent of 1,000 $TCID_{50}$ (tissue culture infectious doses) of measles virus vaccine expressed in terms of the assigned titer of the FDA Reference Measles Virus, and approximately 25 mcg neomycin.
BIAVAX®II (Rubella and Mumps Virus Vaccine, Live, MSD)—Single-dose vials of lyophilized vaccine, 0.5 ml when reconstituted as directed and containing not less than 1,000 $TCID_{50}$ of rubella virus vaccine, live, and 5,000 $TCID_{50}$ of mumps virus vaccine, live, expressed in terms of the assigned titer of the FDA Reference Rubella and Mumps Viruses, and approximately 25 mcg neomycin.
MERUVAX®II (Rubella Virus Vaccine, Live, MSD)—Single-dose vials of lyophilized vaccine, 0.5 ml when reconstituted as directed and containing not less than the equivalent of 1,000 $TCID_{50}$ of rubella virus vaccine expressed in terms of the assigned titer of the FDA Reference Rubella Virus, and approximately 25 mcg neomycin.
M-M-R®II (Measles, Mumps and Rubella Virus Vaccine, Live, MSD)—Single-dose vials of lyophilized vaccine, 0.5 ml when reconstituted as directed and containing not less than 1,000 $TCID_{50}$ of measles virus vaccine, live, attenuated, 5,000 $TCID_{50}$ of mumps virus vaccine, live, and 1,000 $TCID_{50}$ of rubella virus vaccine, live, expressed in terms of the assigned titer of the FDA Reference Measles, Mumps, and Rubella Viruses, and approximately 25 mcg neomycin.
M-R-VAX®II (Measles and Rubella Virus Vaccine, Live, MSD)—Single-dose vials of lyophilized vaccine, 0.5 ml when reconstituted as directed and containing not less than 1,000 $TCID_{50}$ of measles virus vaccine, live, attenuated, and 1,000 $TCID_{50}$ of rubella virus vaccine, live, expressed in terms of the assigned titer of the FDA Reference Measles and Rubella Viruses, and approximately 25 mcg neomycin.
MUMPSVAX® (Mumps Virus Vaccine, Live, MSD)—Single-dose vials of lyophilized vaccine, containing when reconstituted not less than 5,000 $TCID_{50}$ of mumps virus vaccine expressed in terms of the assigned titer of the FDA Reference Mumps Virus, and approximately 25 mcg neomycin.
Each of these vaccines is supplied as a single-dose vial with a disposable syringe containing diluent and fitted with a 25-gauge, ⅝" needle, and as a box of 10 single-dose vials with an accompanying box of 10 diluent-containing disposable syringes with affixed needles.

Denouement and Discussion

Metaphyseal Chondrodysplasia, Schmid Type

Fig 1.—Top left, top right, bottom left, bottom right, Short stature, short limbs, and bowed legs.

Fig 2.—Widening and irregularity of metaphysis and coxa vara.

Manifestations

Major clinical manifestations include dwarfism of the short-limbed type, bowed legs, waddling gait, and normal head size. The bowing of the legs is noted prior to ambulation. The head circumference is usually normal. Coxa vara (responsible for the waddling gait) and genu vara are present. Adult height is in the range of 140 cm. Roentgenographic findings consist of widening, cupping, scalping, and irregularity of the metaphysis, which are more marked in the lower limbs, coxa vara, genu vara, and minimal, if any, epiphyseal, diaphyseal and spinal changes. There are other types of metaphyseal chondrodysplasias (eg, Jansen and McCusick types).

Genetics

This type of metaphyseal chondrodysplasia is inherited as an autosomal dominant trait.

Treatment

Treatment consists of orthopedic surgery when indicated, physical therapy, and genetic counseling.

Radiological Case of the Month

Lionel W. Young, MD; Contributed by MAJ Paul G. Faucher, DO, MC, USA, MAJ A'Delbert Bowen III, MD, MC, USA

A 10-year-old boy was well until ten days prior to admission, when he had intermittent back and neck pain. The pain became more severe and eventually prevented him from getting out of bed. There was no history of trauma. On admission to the hospital, he was in moderate distress, with a straight back and torticollis. Neurological findings were normal and there were no signs of infection. Cervical spine roentgenograms (Fig 1) were obtained.

Figure 1.

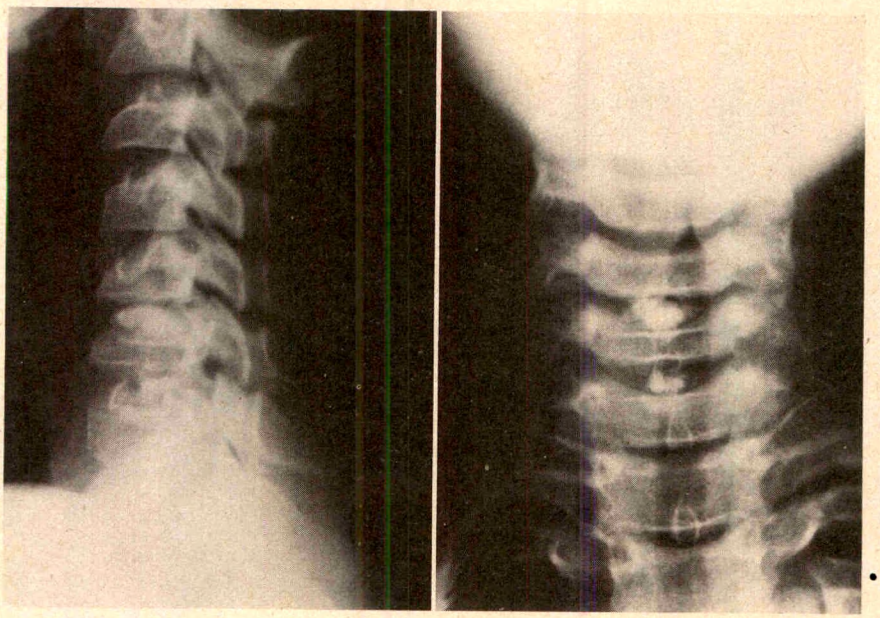

Fig 1.—Calcifications of the nucleus pulposus are present between C-5 and C-6 and between C-6 and C-7. The C-5 and C-6 vertebral bodies are reduced in height.

Fig 2.—Five weeks after initial examination. Note dissolution of calcification from C-6 disk.

Cervical Disk Calcification in Childhood

Calcification of the intervertebral disks in childhood is an uncommon but well-described entity occurring preponderantly in boys between 2½ and 11 years of age, the average being 8 years.[1] The cause is unknown although it has occurred in association with congenital cardiac lesions, infection, ruptured intervertebral disks, bilateral cataracts, chalasia, and trauma.[2] The disease is self-limiting. The C-6 disk is the one most commonly affected.[1]

The duration of calcification prior to the onset of symptoms is seldom known because roentgenograms predating symptoms in most instances are not available. The variable course has been gradual disappearance of the calcification during periods from several weeks to years.[1-4] Some observers believe that pain, low-grade fever, leukocytosis, and elevated ESR signal the onset of resorption of the calcification.[5] In the present case, symptoms and signs abated notably after two days of use of a cervical collar and bed rest. On roentgenograms five weeks later, calcification had diminished in the C-5 disk and was no longer visible in the C-6 disk (Fig 2).

In addition to the disk calcification, flattening or wedging of adjacent vertebral bodies has been noted occasionally.[2,3] Anterior or posterior herniation of the calcified disk is a little known complication that may occur in the course of the disease. Spontaneous resorption of the herniated portion of the disk and remission of symptoms after conservative management is the rule.[5] Neurological deficit is rare; one case of transverse myelitis that resolved spontaneously[6] and four cases of neurosurgical intervention[7] for progressive neurological deficit have been reported. Surgery is rarely indicated.[4]

Differential diagnosis includes ochronosis, vitamin D intoxication, and degenerative disk disease. Whereas calcification of the idiopathic variety is centrally located in the nucleus pulposus, calcification in vitamin D intoxication occurs in the annulus fibrosus.[7] Calcifications of degenerative disk disease and ochronosis are usually not manifested until adulthood.

Clinical Memoranda

CSF Eosinophilia During an Acute Coxsackie B4 Viral Meningitis

Eosinophils have been present in the CSF during the course of a variety of parasitic and nonparasitic diseases.[1] To our knowledge, the only viral infection associated with the presence of eosinophils in the CSF has been a chronic meningitis owing to lymphocytic choriomeningitis (LCM) virus in a 2½-year-old child.[1,2] The diagnosis in the patient with LCM viral meningitis was made on the basis of serologic evidence as the virus could not be isolated. We have recently seen an acutely ill child with eosinophils in the ventricular CSF, a CSF pleocytosis, and a coxsackie B4 viral infection documented both serologically and by viral isolation.

Report of a Case.—A 13-month-old male infant was admitted after a prolonged generalized seizure that required ventilatory support. Several hours prior to admission he had a fever, cough, and vomiting. His medical history included the repair of an aortic coarctation at 2 days of age and the insertion of a ventriculoperitoneal (VP) shunt at 3 months of age for porencephaly. His growth and development had been normal. Prior to his admission, he had been receiving digoxin and phenobarbital sodium.

On examination, he was lethargic but had an appropriate response to pain and moved all extremities well. His temperature was 38.3 °C; pulse rate, 138 beats per minute; respiratory rate, 36/min; and blood pressure, 100 mm Hg. He had a discrete maculopapular rash on the lower part of the abdomen and perineum, and his shunt was not obstructed. Other pertinent physical findings included mild nuchal rigidity, a liver edge palpable at 4 to 5 cm below the right costal margin, and a spleen palpable at 3 cm below the left costal margin.

Laboratory investigations disclosed the following values: hemoglobin, 13.3 g/dL; hematocrit, 40%; and WBCs, 10,600/cu mm. The differential cell count was 61% segmented neutrophils, 29% band forms, 7% lymphocytes, 3% mononuclear cells, and the platelet count was 268,000/cu mm. Ventricular CSF obtained through the shunt and examined using Wright's stain had an RBC count of 20/cu mm and a WBC count of 407/cu mm, with 88% mononuclear cells, 11% eosinophils, and 1% segmented neutrophils. The CSF glucose level was 76 mg/dL (4.22 mM/L) with a simultaneous blood glucose level of 107 mg/dL (5.94 mM/L). The CSF protein value was 140 mg/dL. Simultaneous lumbar CSF showed the following values: RBCs, 8,400/cu mm; and WBCs, 6/cu mm, with 4 mononuclear cells and 2 segmented neutrophils. The SGPT value was 10 units/L. Since the diagnostic impression was aseptic meningitis, no antibiotics were given.

Within six hours, his activity and behavior had returned to normal. Although a low-grade fever persisted, all blood and CSF bacterial cultures were negative. He was discharged after 48 hours.

Three weeks later, he was readmitted with a prolonged seizure. No fever, rash, or hepatosplenomegaly were found. The ventricular CSF obtained through the shunt yielded a WBC count of 5/cu mm, three of which were mononuclear cells and two of which were segmented neutrophils. The CSF protein level was 49 mg/dL, and the CSF glucose level was 60 mg/dL (3.33 mM/L), with a simultaneous blood glucose value of 125 mg/dL (6.94 mM/L). No antibiotics were given and all bacterial cultures were negative. Phenytoin sodium was added to his anticonvulsant medications, and since then, he has had no seizures.

During his first admission, a rectal swab yielded coxsackie B4 virus growth, and the complement fixing (CF) titer to that virus was $< 1:8$. A convalescent CF titer obtained during his second admission was 1:256.

Comment.—Eosinophils have been found in the CSF during the course of chronic bacterial, fungal, viral, and helminthic CNS infections.[1-5] They have also been detected during the course of lymphomas and encephalomyelitis and after the injection of foreign proteins into the CSF.[1,2] Three patients who had eosinophils develop in the CSF between 30 and 40 days after the insertion of rubber catheters for ventricular-cisterna magna CSF shunting have also been described.[6,7] The pathogenic importance of eosinophils in the CSF is unclear. In many instances, there has been no peripheral eosinophilia, suggesting that a local hypersensitivity reaction may be responsible.

The patient described here had a silicone elastomer VP shunt inserted ten months prior to his acute coxsackie B4 viral infection. This infection was associated with fever, cough, vomiting, a seizure, rash, and hepatosplenomegaly. A pleocytosis, eosinophils, and an elevated protein level were present in the ventricular CSF, and the lumbar CSF was abnormal in that two segmented neutrophils were present. Three weeks later, he was well, and although the shunt was still present, the ventricular CSF contained only five cells, no eosinophils, and a decreased protein concentration. These findings suggest that the VP shunt was not the cause of the CSF eosinophils.

To our knowledge, the presence of eosinophils in the CSF during an acute viral infection has not previously been reported. Examination of CSF using Wright's or Giemsa's stains, which stain both acidophilic and basophilic cellular structures, should help to determine the incidence of this finding during viral meningitis.

Ebstein's Anomaly of the Tricuspid Valve Associated With Prenatal Exposure to Lithium Carbonate

Congenital malformations have been previously reported in infants born to women who received lithium carbonate during pregnancy.[1] Although this drug has been used in

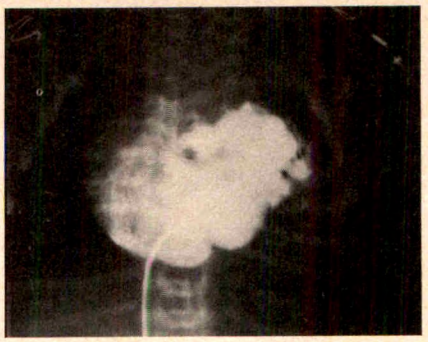
psychiatric therapy since 1949 and has received attention as a possible human teratogen, evidence relative to its teratogenicity on human fetuses is inconclusive. In 1974, Nora et al reported two cases of Ebstein's anomaly of the tricuspid valve in infants whose mothers had received lithium during pregnancy and suggested that the incidence of this rare cardiac defect is strikingly high among such babies.[2] The purpose of our report is to describe another patient in support of the contention that lithium is a potent cardiovascular teratogen.

Report of a Case.—A female infant was delivered at term to a 25-year-old primigravida who had taken 1,200 mg of lithium carbonate daily throughout her entire pregnancy for manic-depressive symptoms. The mother denied taking any other medication during her pregnancy, and there was no known family history of congenital heart disease. At delivery, the baby was noted to have cyanosis, and a heart murmur was heard. Oxygen was administered without demonstrable clinical improvement. The baby was referred to us on the first day of life for further examination.

Physical examination showed a neonate with severe cyanosis who measured 53 cm in length and weighed 4,200 g. The heart rate was 160 beats per minute and the respiratory rate was 60 breaths per minute. The blood pressure by Doppler was 56/24 mm Hg. Peripheral pulses were normal. There was a quadruple rhythm, and a grade 3/6 pansystolic murmur was loudest at the left lower sternal border. The lungs were clear to auscultation. The liver edge was palpable 3 cm below the right costal margin at the midclavicular line. The results of the rest of the physical examination were normal and there was no evidence of additional malformations.

A chest roentgenogram showed a distinctly enlarged heart with diminished pulmonary vascular markings. An ECG showed sinus rhythm with a rate of 140 beats per minute and mean frontal QRS complex axis of +110 degrees. The PR interval was prolonged, with evidence of right atrial enlargement and right ventricular conduction delay. Data from cardiac catheterization and angiocardiography (Figure) were characteristic for Ebstein's anomaly of the tricuspid valve with severe tricuspid valve insufficiency, distinct dilation of the right ventricular outflow tract, and patent ductus arteriosus. She was given digoxin and her condition was clinically improved prior to discharge from the hospital on the fourth day of life.

She has since experienced multiple episodes of paroxysmal supraventricular tachycardia. At 1 year of age she is under close observation while receiving digoxin (Lanoxin) and propranolol hydrochloride (Inderal).



Right ventriculogram shows severe tricuspid valve insufficiency, extreme dilation of right ventricular outflow tract, and "atrialized" right ventricle just to left of spine.

Comment.—The teratogenic effects of lithium have been demonstrated experimentally in many animal species.[3,4] Conclusive evidence for its teratogenicity on the human fetus is lacking. Despite the general consensus that associated congenital malformations in fetuses are probably incidental to treatment with lithium during pregnancy,[5] the Register of Lithium Babies indicates that cardiac malformations have been encountered more frequently than would be expected.[1] Thirteen of 143 infants born to mothers who received lithium during their pregnancy had recognized congenital malformations. Eleven of those infants had cardiovascular defects, including patent ductus arteriosus, mitral atresia, coarctation of the aorta, tricuspid atresia, ventricular septal defect, and Ebstein's anomaly of the tricuspid valve (four cases). In addition, Rane et al reported a case with dextrocardia and coarctation of the aorta.[6] Review of the report of 12 "lithium babies" with cardiovascular anomalies suggests that at least three of the mothers had received no drugs other than lithium. Six of these mothers also received other drugs during their pregnancy, thereby making it difficult to prove that lithium was solely responsible for their infant's cardiovascular malformations. The reported frequency of Ebstein's anomaly is approximately one in 20,000 live births[2]; therefore, it is especially noteworthy that four cases of Ebstein's anomaly have been reported to the Register of Lithium Babies.[1] Nora et al were the first to stress the strikingly high frequency of such a rare defect in "lithium babies," thus implying that this drug can be a potent cardiovascular teratogen in susceptible persons.[2]

Our case had Ebstein's anomaly of the tricuspid valve with documentation that the mother had received no drugs other than lithium during her pregnancy. This case provides additional evidence to support the view that lithium is a potent cardiovascular teratogen. Extreme caution should be exercised to avoid the use of the drug in pregnant or potentially pregnant women.

Migration of Inflorescence: Complications of Grass Head Aspiration

Foreign body aspiration may cause acute airway obstruction or chronic and recurrent inflammation of the lung. An unusual aspiration syndrome has been described as following inhalation of the inflorescence, or flower-bearing part, of grasses.[1,2] Structural characteristics of the grass head predispose it to peripheral migration, making spontaneous expectoration unlikely. The length and stiffness of

the spines radiating from the inflorescence dictate its behavior after aspiration. Peripheral migration with airway obstruction characterize timothy grass heads, whereas barley grass heads tend to continue migration through the lung parenchyma and chest wall.

The following case illustrates the complications that may occur after aspiration of a barley grass head. The possibility of foreign body aspiration was not considered in our patient until the inflorescence was found in the pleural cavity.

Report of a Case.—This previously healthy 2½-year-old child had an acute onset of dyspnea and fever. A chest roentgenogram showed a right lower lobe infiltrate, and treatment with oral erythromycin ethylsuccinate was begun. A right pneumothorax was demonstrated the next day when he returned with increasing dyspnea. He was admitted to the local hospital for treatment with parenteral penicillin G potassium. A third chest roentgenogram 24 hours after admission showed a right pleural effusion and therapy was again changed to intravenous methicillin sodium after chest tube placement. A small amount of purulent pleural fluid was obtained and a few Gram-positive cocci were reported on smears stained with Gram's stain. Response to therapy was poor and three days later he was transferred to USAF Medical Center Keesler, Keesler AFB, Miss.

Initial examination revealed a mildly distressed, toxic-appearing child with a temperature of 39.7 °C. Chest roentgenogram at the time of admission showed a large right pleural effusion with a small residual pneumothorax. A tuberculin test was placed, which was nonreactive at 48 hours. Initial WBC count was 27,700/cu mm, with 65 polymorphonuclear leukocytes, eight band forms, 24 lymphocytes, and three mononuclear leukocytes; the hemoglobin level was 8.8 g/dL.

The patient was taken to the operating room, where a right thoracotomy was performed to drain the pleural effusion and place two chest tubes. Cultures of the effusion were obtained for aerobic and anaerobic bacteria, mycobacteria, and fungi. Staining with Gram's stain of the cloudy yellow fluid showed a predominance of small Gram-positive cocci, small Gram-negative rods, and a few larger Gram-negative rods. Broad spectrum antimicrobial treatment was initiated using methicillin sodium, 200 mg/kg/day; gentamicin sulfate, 7.5 mg/kg/day; and chloramphenicol sodium succinate, 100 mg/kg/day.

Temperatures to 40 °C were recorded daily over the next 48 hours. Because of the lack of clinical improvement, a repeat right thoracotomy with extensive decortication of a thick fibrin-pleural peel was accomplished. A foreign body, the stalk and tuft of field grass (Figure), was found in the right pleural cavity overlying the diaphragm. Bronchoscopy was performed and was normal.

Progressive improvement in the patient's condition was observed over the next two weeks while he received antibiotics and chest tube drainage. Pleural fluid cultures grew the following organisms: *Hemophilus segnis*, *Peptococcus* sp, *Bacteroides* sp, and *Peptostreptococcus* sp.

No history suggestive of aspiration could be elicited from the parents. The child has remained healthy over the seven-month follow-up period.

Comment.—The acute onset of respiratory distress, pneumothorax, and pleural effusion in this child suggested aspiration of a foreign body with migration through the lung into the pleural cavity. The organisms isolated from the pleural cavity are common inhabitants of the oral cavity and may have been carried to this site by the grass head.[3] Other sources of a polymicrobic infection of the pleural space were considered, including hepatic and lung abscess. Broad spectrum antimicrobial agents were used, but adequate surgical drainage and removal of the foreign body were required before improvement occurred.

History suggestive of an aspiration episode was not obtained from the parents of this child. Even with a suggestive history, bronchoscopy may be unrevealing because of the rapid peripheral movement of grass heads. Barley grass heads have been found as unexpected inhabitants of chest wall abscesses.[4,5] Migration of the grass head was suggested by Ross to occur through bronchi that allow penetration of the pleura at a right angle with progression into the chest wall.[6] An alternate angle of impact to the pleura may allow intrapleural seeding. The latter course is unusual, as evidenced by the small number of patients reported with intrapleural foreign body. Three children with lung abscess and empyema associated with an intrapleural foreign body have been described.[2,7] Another report described an adult with seven years of pulmonary problems who was found to have an intrapleural barley grass head at the time of thoracotomy.[6]

Timothy grass heads differ from the type found in our patient, in that stiff, radiating spines are lacking. Aspiration of this type of grass head causes an obstructive problem without further migration to the chest wall. Surgical removal of a portion of the lung may be necessary, as the rapid peripheral movement usually precludes bronchoscopic retrieval.[8] The unexpected finding of a grass head in a surgical specimen has also been reported.[9]

Stalk and tuft of field grass found in patient's right pleural cavity overlying the diaphragm at time of operation.

Aspiration of the grass inflorescence is an unusual occurrence. The clinical picture after this type of foreign body aspiration differs from that characteristically associated with other aspiration syndromes. Localized emphysema and atelectasis are unusual, as air will move around and through grass heads.[10] Rapid peripheral migration makes bronchoscopic retrieval less likely, even with repeated attempts. Morbidity after aspiration of obstructive grass heads, such as timothy grass, is related to infection and bronchiectasis. Thoracotomy and pneumonectomy may be required for resolution. Barley grass heads most commonly appear as a chest wall abscess, but may cause serious problems, as illustrated by our patient. Patients with a history of grass head aspiration and negative bronchoscopy may require thoracotomy to prevent these complications.

Spinal Cord Compression: An Unusual Manifestation of Pseudohypoparathyroidism

Pseudohypoparathyroidism is a disorder characterized by typical somatic features, hypocalcemia, hyperphosphatemia, elevated circulating levels of parathormone (PTH), and unresponsiveness to parathyroid injection.[1,2] Although the clinical and roentgenographic features of this condition have been the subject of various reports and reviews,[1,3] abnormalities of the spine are rarely described. In this report, we present a patient with pseudohypoparathyroidism who had spinal cord compression owing to bony narrowing of the spinal canal.

Report of a Case.—A 3-year 10-month-old boy was evaluated for short stature and developmental delay. His birth history and medical history were unremarkable. There was no history of seizures or tetany. The mother was found to have pseudo-pseudohypoparathyroidism based on clinical and biochemical features and confirmed by normal urinary adenosine 3′:5′-cyclic phosphate (cAMP) response to parathyroid injection.[2] He was short (height age, 1 year and 10 months) and obese, and he had rounded facies and small and broad hands with stubby fingers. Severe psychomotor retardation was noted. His strength, muscle tone, and deep-tendon reflexes were normal. The serum calcium level was 8 mg/dL; phosphorus, 7.9 mg/dL; PTH, 285 μLEq/mL (normal, 0 to 10 μLEq/mL). An intravenous infusion of 200 μ of bovine parathyroid injection failed to increase the urinary excretion of phosphate and of cAMP.

Roentgenographic studies of the skull indicated no intracranial calcifications; the basal angle of Welcker was 143 °, indicating platybasia[4]; films of the pelvis showed mild bilateral coxa valga; hand films showed decreased bone density, coarse trabeculation, short metacarpals, and short phalanges. The bone age of 5 years was substantially advanced. He was treated with dihydrotachysterol, but compliance was poor, and he had persistent hypocalcemia (7.3 to 8 mg/dL) and hyperphosphatemia (7.9 to 8.5 mg/dL) during the following months.

At 4½ years, he was admitted to the hospital for evaluation of progressive decline of motor functions, which had begun two months previously with difficulty in moving his arms. Subsequently, there was gradual loss of his ability to walk, stand, and sit unsupported. He had no change in bladder or bowel function. There was no history of trauma or febrile illness. Neurological examination revealed intact cranial nerves and severe quadriparesis. His serum calcium level was 8.0 mg/dL and serum phosphorus value was 5.1 mg/dL. Roentgenograms of the spine showed a striking reduction in the sagittal diameter of the spinal canal at the level of C-3 and C-4, which measured, respectively, 9.5 mm and 10 mm[5] (Figure). Narrowing of the canal was also evident in the lumbar region, with severe reduction of the interpediculate distances, ranging from 15.5 mm at the level of L-5 to 17 mm at L-1.[6] Osteoporosis was not present. A myelogram depicted a narrow thecal sac in the lumbar and cervical regions, with nearly complete block from the C-2 to C-6 levels.

The patient underwent laminectomy from C-2 to C-5; the dura was tense and bulging, with pulsation returning after decompression. There was partial recovery of motor function after surgery. Thus, one year later, he uses his arms to feed himself, is able to sit briefly unsupported, but has severe spasticity of the lower extremities.

Lateral view of cervical spine. Notice reduction of sagittal diameter of cervical canal, more striking (arrows) at C-3 (9.5 mm) and C-4 (10 mm).

Comment.—In 1942, Albright et al described a syndrome of a characteristic phenotype, clinical signs of hypoparathyroidism and evidence of peripheral resistance to parathyroid extract.[1] Subsequently, Chase et al observed that patients with pseudohypoparathyroidism have a lack of or defective PTH-sensitive adenyl cyclase in renal tissue, and they assumed that the metabolic defect in bone would be of a similar nature.[2] Drezner et al, however, suggested that the hypocalcemia and the bone disease in this condition are due to a state of vitamin D deficiency, resulting from inability of the kidney to convert 25-hydroxycholecalciferol to 1,25-dihydroxycholecalciferol.[7] Nevertheless, the basic osseous abnormalities in pseudohypoparathyroidism are distinct from those encountered in other states of vitamin D deficiency and seem to be genetically determined. Most frequently, they include thickened calvaria, shortening of the metacarpals, coxa valga, exostoses, and advanced bone maturation.[3] Our patient had several of these typical changes, in addition to which severe abnormalities in the skull and spine were present. To our knowledge, platybasia has not been reported in association with pseudohypoparathyroidism, and its occurrence, in our patient, remains unexplained. Roentgenographic changes of the spine are seldom described. Decreased sagittal diameter of the lumbar vertebral canal has been previously described in a patient with this condition,[8] and Cullen and Pearce have described spinal cord compression in a patient who

was found to have excessive bone formation inside the vertebral canal.[9] Spinal cord compression owing to bone overgrowth has also been noted by Highman et al in adult patients with vitamin D-resistant osteomalacia.[10] These authors speculated that treatment with vitamin D or dihydrotachysterol may have stimulated further bone deposition and caused compression of the cord in a spinal canal already narrowed by the basic process. Likewise, it is possible that treatment with dihydrotachysterol in our patient aggravated preexisting abnormalities of the spinal canal, or that therapy may have been solely responsible for those changes. Alternatively, we believe that the bony thickening of the spinal canal may, in fact, be part of the osseous changes that are genetically determined in pseudohypoparathyroidism.

Structural changes of the spine in pseudohypoparathyroidism may be more common than currently appreciated. The findings from our patient probably represent the severe end of a spectrum of osseous changes not yet explored in detail. Roentgenographic studies of the skull and spine and careful neurological examinations should be considered in the assessment and follow-up of patients with this condition.

Complications of Propranolol Use in Neonatal Thyrotoxicosis

Neonatal thyrotoxicosis presents a difficult management problem. Recent reports have proposed that neonatal thyrotoxicosis may be effectively and safely treated with propranolol hydrochloride alone.[1,2] Smith and Howard's report emphasized that their patient did not show clinical improvement while receiving iodides, thioamides, and phenobarbital until the addition of propranolol.[3] A recent article has suggested that "beta blockade should be the treatment of choice for neonatal thyrotoxicosis."[4] However, we would like to report a case in which propranolol used alone for this purpose caused episodic bradycardia without otherwise improving the patient's clinical status.

Report of a Case.—The patient was a 2,170-g female infant born at 37 weeks' gestation to a 22-year-old multigravida referred to the St Paul (Minn) Ramsey Perinatal Center. One year prior to delivery, the infant's mother had been treated with radioactive iodine for hyperthyroidism. She received 50 μg daily of levothyroxine sodium (Synthroid Tabs) during this pregnancy. At birth, the infant was small for gestational age and had a head circumference of 29.5 cm. No other abnormalities were noted. At 20 hours of age, the infant became jittery, tachypneic, and tachycardiac. Phenobarbital sodium therapy was initially begun because of concern of possible drug withdrawal. No evidence of drug withdrawal was subsequently found. Bacterial cultures were obtained and were negative.

At 36 hours of age, the infant had loose, yellow stools occurring ten to 15 times per day. Beginning at 3 days of age, she displayed a voracious appetite, consuming more than 200 calories per kilogram per day. But by the fifth day of life, she weighed 110 g less than her birth weight. At 5 days of age, the serum T_4 value (radioimmunoassay) was greater than 24.5 μg/dL. Reexamination at this time disclosed a jittery, plethoric, small infant. Heart rate varied between 130 to 200 beats per minute; respiratory rate was 60 to 70/min. The infant's axillary temperature intermittently increased to 37.5 °C. The eyelids were slightly puffy, but there was no exophthalmos. Thyroid tissue was palpable just above the sternal notch. There was no evidence of congestive heart failure.

Therapy with propranolol hydrochloride, 2 mg orally every 12 hours, was begun. Phenobarbital therapy was stopped. Twenty-four hours later, propranolol hydrochloride was increased to 2 mg every eight hours. With the increase in the dosage of the drug, episodes lasting 10 to 15 s of heart rates between 80 to 90 beats per minute (sinus bradycardia by ECG) were noted. These episodes were most frequent two to four hours after propranolol administration. Between these episodes, the heart rate was 120 to 170 beats per minute. Despite the episodic bradycardia, the infant's status otherwise was unchanged.

At 8 days of age, propylthiouracil, 4 mg every eight hours, and strong iodine solution (Lugol's solution), one drop every eight hours, were added to the regimen. Three days later, the infant started to gain weight, had less diarrhea, and was less irritable. Frequent episodes of sinus bradycardia continued, however, and at 14 days of age, the propranolol therapy was discontinued. The serum T_4 value at this time was 14.2 μg/dL. Thereafter, the heart rate was consistently greater than 120 beats per minute. The infant continued to show improvement and was discharged at 3 weeks of age on a regimen of propylthiouracil and strong iodine solution. Propylthiouracil therapy was continued for six months. At 8 months of age, the infant is no longer receiving any medication, and she is clinically and chemically euthyroid. She is growing along the fifth percentile, and she is showing age-appropriate development.

Comment.—Propranolol may control the signs and symptoms of hyperthyroidism, and it has been successfully used in the treatment of neonatal hyperthyroidism. For these reasons, we elected to treat our patient with this drug. Unlike other reported cases, however, our patient did not show rapid clinical improvement. Bradycardia occurred several times each day, and this undesirable effect did not abate until propranolol therapy was stopped. Only with the addition of iodides and propylthiouracil to the regimen did the baby's symptoms of irritability, diarrhea, weight loss,

tachypnea, and tachycardia show improvement.

Propranolol, a β-adrenergic antagonist, has many pharmacological effects. Pulse rate seems to be especially sensitive to the action of this drug. Negative chronotropic changes in normal adults given propranolol are more profound and long lasting than are inotropic changes.[5,6] Sensitivity of heart rate to this drug is also apparent in thyrotoxicosis. Mazzaferri et al treated hyperthyroid adults with propranolol alone and noted no difference in pulse rate between them and euthyroid controls.[7] However, other evidence of hyperthyroidism was still apparent in most of their patients. Other studies have confirmed that although pulse rate may be normalized or palpitations may be controlled with propranolol, other signs and symptoms of hypermetabolism may continue.[8-10]

Our patient's intermittently slow heart rate with evidence of otherwise inadequate β-blockade probably represents another example of the disparity between the chronotropic action of propranolol and its other effects. The possibility that this infant had an idiosyncratic response to the drug cannot be excluded.

In mild cases of neonatal hyperthyroidism (as manifested only by tachycardia), small doses of propranolol might be appropriate. In infants who are more seriously ill, other drugs may have to be used to ensure a satisfactory clinical response. In these instances, propranolol should not be considered the only drug of choice. Administration of propranolol, whether used alone or in conjunction with other therapeutic agents, makes continuous cardiac monitoring mandatory.

Diphtheroid Sepsis in a Child With No Predisposing Condition

Diphtheroids – *Corynebacterium* species other than *C diphtheriae*–are ubiquitous organisms and rarely pathogenic. When isolated in cultures of blood and other usually sterile body sites, diphtheroids are commonly dismissed as contaminants.[1] In 1978, diphtheroids accounted for 3.2% of positive blood cultures and grew from 0.2% of all blood cultures (4,000) at the Montreal Children's Hospital (MCH).

A child, recently hospitalized at the MCH for evaluation of fever of unknown origin, was discharged without a diagnosis. The growth of diphtheroids in two of seven blood cultures was dismissed as unimportant because the child did not seem to be a compromised host and no apparent nidus of infection could be found. Subsequent events proved that these diphtheroids were the cause of his illness. The purpose of this report is to encourage the critical evaluation of *all* isolates from normally sterile sites such as blood, CSF, and bone marrow.

Report of a Case.–An 8½-year-old boy was admitted to the MCH to evaluate a fever of ten days' duration, accompanied by a frontal headache, malaise, anorexia, and irritability. The past medical history and review of systems as well as detailed travel, contact, and environmental histories were unremarkable. On admission, he was pale, thin, irritable, and had a temperature of 39 °C. The only abnormal physical findings were a grade 1-2/6 nonradiating systolic ejection murmur over the pulmonic valve area, sustained ankle clonus, and hyperreflexia of the knee and ankle.

By day 3 of hospitalization, the results of the neurological examination had become normal and the murmur had been assessed as physiologic by the cardiologists. The patient, however, remained febrile and irritable. Blood cultures were collected almost daily while the following laboratory data were obtained: a hemoglobin concentration of 9.8 g/dL; a peripheral WBC count of 9,100/cu mm, with 80% neutrophils and 5% band forms; a normal number of platelets; and an ESR of 64 mm/hr. Lumbar CSF was normal except for the presence of seven WBCs per cubic millimeter, two of which were neutrophils. Results of urinalysis, blood chemistries, immunoglobulin levels, C3, and C4 were all normal. Tests for rheumatoid factor and antinuclear antibody screening test to detect presence of antibodies of five different types of streptococci (streptozyme), slide test for heterophil antibody of infectious mononucleosis, and tests for agglutinins for *Salmonella*, *Brucella*, and tularemia were all negative. Repeated bacterial, viral, and fungal cultures of the urine, throat, and stool did not indicate pathogens. Tuberculin skin tests were negative. Roentgenograms of his chest, sinuses, skull, and gastrointestinal tract, as well as computerized tomography of his head, total body scan using gallium citrate Ga 67, abdominal ultrasound examination, and serial echocardiograms and ECGs were all normal. A bone marrow biopsy specimen showed normal histologic findings.

On day 13 of hospitalization, two sets of blood cultures, drawn 12 hours apart from different sites four days earlier, contained diphtheroids. Subsequent blood cultures were sterile, and the diphtheroids were dismissed as contaminants. On day 18, the patient was discharged shortly before diphtheroids were noted growing from the bone marrow aspirate obtained on day 11.

On examination four days after discharge, the patient was febrile, looked ill, and was found to have left-sided hyperreflexia. The patient was readmitted to the hospital and erythromycin lactobionate therapy was started for presumed diphtheroid endocarditis. (Erythromycin was selected based on the sensitivity patterns of other MCH diphtheroid isolates.) Three days later, because of continuing neurological symptoms and fever, another lumbar puncture was done. The CSF showed diphtheroid growth, whereas a skin swab from the prepared lumbar puncture site was sterile. The only other abnormal finding in the CSF was a protein concentration of 42 mg/dL.

Minimal inhibitory concentrations (MICs) of erythromycin, penicillin G potassium and gentamicin sulfate against the bone marrow and CSF isolates were 128 μg/mL, 0.12 μg/mL, and 0.003 μg/mL. Because of the duration and severity of the patient's illness, combination antimicrobic therapy with penicillin G potassium and gentamicin was begun. Our laboratory, as

well as the Laboratory Center for Disease Control, Ottawa, Ontario, Canada, was unable to further speciate the corynebacteria isolates.

Three days after beginning the appropriate antimicrobics, the patient was afebrile, hungry, and generally feeling well. Repeated CSF and blood cultures were sterile. After 18 days of combined parenteral antimicrobic therapy, the patient was given oral potassium phenoxymethyl penicillin therapy alone, which was continued for five weeks. Although his hemoglobin concentration rapidly returned to normal, his ESR remained elevated for six weeks. By four weeks after discharge from the hospital, the patient had gained more than 3 kg. He continues to be entirely well.

Comment.—Corynebacteria are Gram-positive, nonmotile, catalase-positive, pleomorphic bacilli that are commonly present on normal human skin and mucous membranes and that are part of the normal intestinal flora.[1] Diphtheroids—corynebacteria other than *C diphtheriae*—are generally considered to be nonpathogenic in man. Diphtheroids are not only common contaminants of clinical specimens, but they also are frequently fastidious and slow growing, requiring prolonged incubation.[1] Once the organism is isolated, further speciation may not always be possible, as in this case.

Reports of diphtheroid infections in children generally describe patients with anatomic abnormalities of the heart or CNS or patients after surgery or trauma. The most frequent infections are bacterial endocarditis,[1-3] acute meningitis,[1,2,4] and CSF shunt infections.[2,5,6] Acute meningitis[4] and endocarditis[1-3] have also occasionally been reported in normal children.

Although reports of diphtheroid sepsis are not unusual in adults with malignant neoplasms, diphtheroids are not being reported as a cause of sepsis in similarly compromised children.[1,2,6-8] In a recent review of septicemia in children with acute leukemia, 20% of the blood isolates were either *Staphylococcus albus* or *Propionibacterium acnes* (a diphtheroid).[9] For reasons not stated by the authors, these organisms were excluded from analysis.

The purpose of this report is to emphasize that "nonpathogens" such as diphtheroids can cause serious infections in children. The problem for the clinician is to decide when these organisms are causing disease. The most critical element in making such a diagnosis is a high index of suspicion. Children with congenital abnormalities of the heart or CNS or those receiving immunosuppressive therapy seem to be at highest risk. The situations that should make one wary include the isolation of the same organism from more than one site that is usually sterile, such as blood and CSF, or the isolation of the organism from the same source on repeated occasions.

Meticulously sterile technique during culture collection is also important. In cases where repeated cultures are being collected because previous specimens contained "contaminants," it is useful to culture the prepared site at the same time as the new specimen is obtained.

The laboratory also can be of assistance in evaluating culture results. Although infrequently done, pour-plate cultures, in which 1 mL of blood is added to 15 mL of melted nutrient agar, may be helpful. One or two colonies per milliliter of blood suggests contamination, whereas multiple colonies usually represent bacteremia.[10]

Similarly, if a diphtheroid isolate is considered to be a pathogen, the laboratory can do specific sensitivity testing. This is important since there are wide strain-to-strain variations in antimicrobic sensitivities.[1] If the patient's condition dictates therapy before sensitivities are known, empirical treatment with a penicillin and a chloramphenicol is suggested as many diphtheroids are sensitive to one or both.[1,2,5] However, definitive treatment must be based on the MICs-minimum bacteriocidal concentrations of antimicrobic agents for the isolate.

Focal Cerebral Atrophy in Incontinentia Pigmenti Achromians

Incontinentia pigmenti achromians (IPA), also called hypomelanosis of Ito, is an uncommon cutaneous anomaly. Abnormalities in other organs, including the brain, have been found in about 50% of the patients so far reported.[1,2] Focal, as opposed to generalized, neurological symptoms have rarely been described although previous reports have been limited to the dermatological literature and neurological investigations have not been adequate to establish the nature of the brain lesions. This is a description of a patient with IPA who had focal cerebral atrophy.

Report of a Case.—A 13-year-old black boy was referred for neurological evaluation because of the recent onset of seizures. He had been born at full term after an uneventful pregnancy and delivery. The neonatal period was complicated by jaundice and a blood transfusion. At 4 months of age, his mother noticed an irregular area of hypopigmentation on the right thigh, which extended during the next several years to the right hip and buttock. Early developmental landmarks were normal, but since beginning grade school, he had attended special education classes.

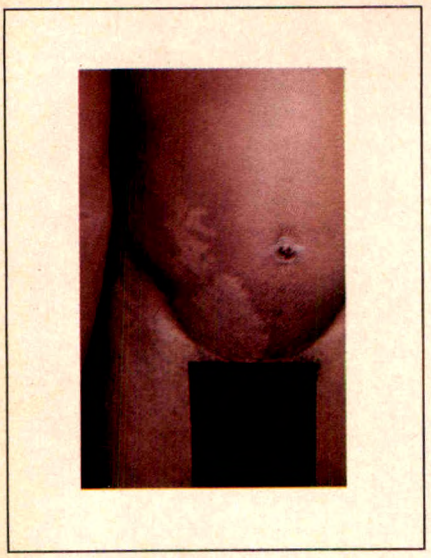

Fig 1.—Irregular, patchy areas of hypopigmentation over patient's right lower side of abdomen and thigh are characteristic of incontinentia pigmenti achromians.

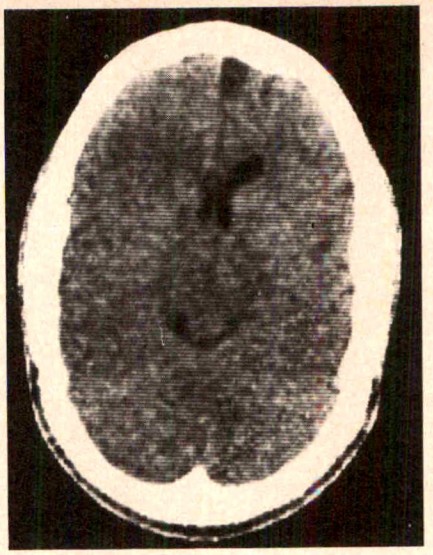

Fig 2.—Dilated frontal horn of left lateral ventricle and widened sulci on computerized tomographic brain scan indicate left frontal atrophy.

Six months before evaluation, he started to have seizures once or twice each month. These consisted of staring and clonic jerking of the right hand that then became generalized. There was no history of seizures, mental retardation, or skin lesions in his family, who included one younger sister and one younger brother.

On dermatological examination, there was unilateral patchy and speckled hypopigmentation extending from the umbilical area over the lower part of the abdomen to the buttock and the right thigh (Fig 1). Wood's lamp examination indicated no other changes. The rest of the results of the general medical examination, including dentition, were normal.

On neurological examination, he missed double simultaneous stimulation on the right hand and face, but other tests of parietal sensation and the rest of the neurological examination showed no abnormalities. Neuro-ophthalmological examination results, including those for visual acuity, fields, and funduscopic examination, were normal.

Biopsy specimens were taken of hypopigmented and normal skin. Hematoxylin-eosin and Fontana-Masson stains were performed, and frozen sections were studied by the dopa technique. In the specimen of hypopigmented skin, the amount of melanin was decreased and the dopa reaction was weaker in the basal layer of the epidermis. There was no incontinence of melanin granules into the dermis, and no inflammation. Electron microscopy showed a reduction in the number of melanosomes in the basal melanocytes.

Psychometric testing included the Wechsler Intelligence Scale for Children-Revised, Halstead-Reitan neuropsychological test battery, Wechsler Memory Test, and the Aphasia Screening Test. Full-scale IQ was 54 (verbal IQ, 58; performance IQ, 58). There was a prevalence of errors in the processing of language and language symbols.

The EEG demonstrated focal spike discharges in the left temporal and parietal head regions, with associated persistent focal polymorphic delta activity. Computerized tomographic (CT) brain scan demonstrated left frontal atrophy (Fig 2). The CSF and the skull roentgenograms were normal.

The patient's seizures were controlled by phenobarbital sodium and phenytoin sodium. Results of follow-up dermatological and neurological examinations, skin biopsy specimen, psychometrics, EEG, and CT scan performed one year later were unchanged.

Comment.—The diagnosis of IPA is based on the characteristically irregular, swirling hypopigmentation found on clinical examination. This may affect any part of the body, unilaterally or bilaterally. Decreased melanin in the basal epidermis is confirmed by dopa reaction and electron microscopy. In contrast to incontinentia pigmenti, which it resembles, preceding inflammation of the skin does not occur. The disorder is usually not familial.

Abnormalities in other organs, usually the skeleton, eye, and brain, are common. The most common skeletal problems are scoliosis or limb asymmetry. Eye involvement most frequently includes strabismus, choroidal atrophy, or retinal pigmentary changes.[1,2]

One fourth of patients with IPA have mental retardation or seizures, often coexisting in the same patient.[1,2] Other neurological abnormalities, including macrocrania and hypotonia, have been reported.[2-4] Our patient had symptoms and signs of left cerebral hemisphere dysfunction, including language impairment, parietal sensory deficit, focal seizures, and focal abnormalities on the EEG and the CT brain scan. The hypopigmentation of his skin was limited to the right side of the body. With the exception of our patient, focal neurological findings have been mentioned in only two patients, neither studied in detail. Both patients had focal abnormalities on EEG, one with ipsilateral skin lesions[5] and the other with contralateral skin lesions.[4]

This report demonstrates that, in contrast to the Sturge-Weber and linear nevus sebaceous syndromes, focal cutaneous and cerebral abnormalities are not inevitably ipsilateral in IPA. Detailed evaluations of future patients, including CT brain scans, are needed to determine the true frequency and importance of focal neurological lesions in patients with IPA.

Injuries and Child Abuse

Sir.—I was encouraged to see in the JOURNAL (133:906-909, 1979) another article (this by Ellerstein) describing the superficial injuries of abused and neglected children. Minor injuries are more common in this population[1] than major injuries and may antecede them.[2] We have recently published data[3] that expand on Dr Ellerstein's statement, "Multiple bruises of the buttocks or the genital area are not commonly accidental."

Compared to two groups of accidentally injured children, soft-tissue injuries (contusions, abrasions, scratches, and lacerations) were more common in the abused group ($P < .001$) not only over the buttocks and genitalia, but also over the cheeks, neck, trunk, and posterior thigh. Lacerations were almost seven times more common in the accidently injured emergency room group than in the abused group ($P < .001$). Dr Ellerstein's focus on superficial injuries is helpful but his failure to emphasize their distribution "neglects" a useful cue in the diagnosis of child abuse.

Streptococcal Neonatal Osteomyelitis

To the Editor.—Memon et al in a recent issue of the JOURNAL (133:921-923, 1979) emphasized the increasing importance of group B streptococcal neonatal osteomyelitis. Reviewing 23 published cases, they found infection most frequently in the humerus or femur, and occasionally in the talus or tibia. Earlier reports[1] had suggested almost exclusive involvement of the humerus. We recently encountered a case with infection in a previously undescribed location that caused us diagnostic problems.

Report of a Case.—This previously healthy boy was noticed at 13 days of age to be favoring his right leg, holding it flexed at the hip. Two days later fever and irritability developed.

On admission to the hospital, he was febrile (37.7 °C) and irritable, and held his right hip flexed and slightly rotated externally. Movement of the hip obviously caused pain, although the passive range of motion was not limited. An area of cellulitis had recently developed on the dorsum of the right hand. The remainder of the examination results were normal. Roentgenograms of the chest, pelvis, and hips were normal. Lumbar puncture and analysis results revealed normal CSF. The sedimentation rate was 83 mm/hr. Blood cultures subsequently grew group B streptococcus type III.

The right hip joint and femoral metaphysis were aspirated, but no pus was found and cultures of the scant tissue fluids grew no pathogens. The following day, a bone scan with technetium Tc 99m and methylene diphosphate showed increased uptake in the right sacroiliac area, but not in the femur or hand. No physical findings were discernible in the sacroiliac area. Ten days after admission, repeated roentgenograms showed periosteal new bone formation in the medial portion of the right iliac (greater sciatic) notch.

After surgery, antibiotic therapy was initiated with cloxacillin sodium monohydrate, ampicillin sodium, and gentamicin sulfate, and was later revised to penicillin G potassium (200,000 units/kg/day) and gentamicin sulfate (7.5 mg/kg/day for seven days). The area of cellulitis disappeared after two days of therapy and the right hip was freely mobile after three days. He was discharged after 21 days of intravenous treatment and remained healthy during the subsequent three months.

Comment.—Pelvic osteomyelitis is uncommon, causing only 2.5% of the cases in neonates[2] and older children.[3] Diagnosis can be difficult, as the clinical features simulate pyarthrosis of the hip, but passive movement of the hip remains free and point tenderness may be present over the affected area of the pelvis, if accessible. Internal subperiosteal collections of pus may be evident by rectal examination, ultrasound study, or cause displacement of the bladder on an intravenous pyelogram. Radioactive nuclide scanning has been very helpful in revealing sacroiliac infection.[4]

In this patient, pelvic osteomyelitis occurred as a complication of late-onset group B streptococcal bacteremia, a localization to our knowledge not previously described. No predisposing factor was apparent: the baby was not delivered from a breech presentation nor was there any sign of local bruising. As experience increases, group B streptococci will likely prove capable of infecting any bone.

Books

Fifteen Thousand Hours: Secondary Schools and Their Effects on Children, by Michael Rutter, Barbara Maughan, Peter Mortimore, and Janet Ouston, 285 pp, Cambridge, Mass, Harvard University Press, 1979.

We have come a long way from the heady days of the Great Society, when most people seemed to believe that education would solve all of our problems, both intellectual and social. The Coleman Report in 1966 cast the first doubts, and Jencks (*Inequality*) and Averch (*How Effective is Schooling?*) in 1972 seemed to make it official: nothing that schools do really makes any difference. Considering that we spend more on schools than most other state and local governmental functions combined, this is indeed a dreary state of affairs.

Fifteen Thousand Hours has the temerity to question our present conventional wisdom. It is a study of what things do make a difference in pupil outputs in 12 London inner-city secondary schools. In many ways, it is a substantial improvement, methodologically, over previous studies. First, it studies not just one output (which has usually been the score on some standardized test), but looks at measures of attendance, behavior, delinquency, and achievement. This is not a simple cross-sectional study, but one that examines the students over the four to six years they spend in secondary school. The researchers gathered data not only on those things for which it is easy to gather data (a practice that limits the usefulness of much social science research), but actually went into the classroom and observed what was happening. The result of all this is a book that is rich in detail and often convincing in argument. Some details here will give the flavor of their conclusions.

The schools described, and the neighborhoods they serve, sound as if they could be in almost any American inner city. The houses are old, overcrowded, and rundown. The students have high rates of delinquency and low school achievement. Parents are mostly of the lower class, and there is much unemployment. The schools are in old buildings on crowded sites. Although there is more organizational variety among the schools than one would find in the United States (single-sex schools and church-related schools, for example), the programs of instruction in all are administered by the Inner London Education Authority and are quite similar. Nevertheless, there are large differences among the 12 schools in average achievement, attendance, behavior, and delinquency, and these differences remain large even when differences in the characteristics of the children entering the schools are taken into account. These outcome measures were of children at about age 16 years, the age at which compulsory schooling ends and most leave the schools, and the controlled characteristics were measured when these children entered the secondary schools at about age 11 years. The controlled characteristics were "verbal reasoning," as a control on innate ability, and parental occupation as a control on family background.

The researchers then looked at a large number of school variables, and correlated these with the four outcome measures. The first finding was that physical and administrative features of the schools had no apparent influence on outcomes. Sex composition and religious orientation were unimportant. Size of student body and square feet of building space per student showed no effect. Pupil-teacher ratios similarly had no observable influence. When the researchers looked at variables reflecting the schooling process, however, they began to find significant associations. Some variables representing the school's academic emphasis showed significant correlations with some of the outcome measures. Most of the variables that measured teacher actions during lessons (such as percent of teaching time spent on the topic, and number of disciplinary interventions) were significantly correlated with behavior, but not with the other outcome measures. The association between punishment and outcomes was not usually significant, but that between praise and outcome often was.

This brief summary can only hint at the wealth of data that are summarized and discussed in the book. It warms the cockles of an educator's heart to think that what he is doing is having a worthwhile effect on pupils after all. Unfortunately, a few strong words of caution are necessary. First, the study is of just 12 schools. When the school is the unit of analysis, there is a limit to the things that can be held constant while others are explored. Also, of course, one wonders how the findings can be generalized to dissimilar schools. Second, the controls in inputs are not as stringent as one might desire. Scores on verbal reasoning were "held constant" by discarding the top and bottom 25% of the pupils on this measure, and looking at the middle 50%. Similarly, parental occupation, which is supposed to control for family influences, was collapsed into only three occupational categories.

There are a number of other criticisms one might make of the statistical procedures, including the fact that causation cannot validly be inferred from correlation. In the authors' defense, it must be said that they seem to be fully aware of these shortcomings. The problems arise from the nature of the data available, even though this is a thorough, carefully done study in which a massive amount of data was gathered. The study clearly points up the dilemmas facing those who would perform research in the social sciences. The varieties of human behavior are so numerous, and their interactions so complex, that acquiring reliable knowledge in all but the smallest corners is incredibly complicated. This study is an example of a type of research that should be done more often. The results should be read with interest by educators everywhere. They should not be considered proved, however, until a number of other studies are performed that reinforce the findings.

WALTER I. GARMS, PHD

Rochester, NY 14642

Epilepsies of Childhood, by Niall V. O'Donohoe 318 pp, Washington, DC, Butterworth Inc, 1979.

This is an excellent, small volume that covers in a comprehensive fashion almost all aspects of clinical problems in epilepsy. It is also timely in its publication, in that it has been about eight years since Livingston's book was first published, which recently has been the standard pediatrically oriented monograph on epilepsy. Dr O'Donohoe provides comprehensive discussion of the clinical problems, as well as updates our information. In addition to the expected coverage in chapters relating to such problems as "neonatal seizures," and "Major Generalized Epilepsy (Grand Mal)," etc, there is also the very convenient and

concise presentation of a number of special problems in epilepsy, such as "Post-Traumatic Epilepsy," "Epilepsy in the Adolescent," "Learning Problems in Children with Epilepsy," "Epilepsy in Sleep," etc. These issues are presented in brief chapters and provide a balanced account of the particular problem, which is useful for quick reference, rather than burying the information in larger chapters. However, the brief chapter on "Epilepsy in Brain Tumors," although correctly pointing out the rarity of supratentorial tumors in childhood that appear as a seizure problem, does not deal with the occasional but important instances of long-standing epilepsy in childhood (up to 90% of the lifetime of a 10- to 15-year-old child) where tumor is eventually revealed as the cause. This possibility reinforces the importance of alert reassessment of chronic epilepsy patients on follow-up examination.

The advantage of a single author who speaks from a significant personal experience is obvious in monographs of this kind. The bias of the author, however, occasionally shows itself. I was struck by a number of references that indicate he may be too hard on phenytoin, a drug that continues to be very useful despite an increasing list of problems relating to chronic toxicity. A more positive prejudice is the balanced place that the EEG is given in this account. Some would say it is underemphasized; I think, however, that in a presentation to students and pediatricians it is entirely appropriate. In summary then, I am pleased to have a copy of this book and plan to use it.

CHARLES F. BARLOW, MD
Children's Hospital Medical Center
300 Longwood Ave
Boston, MA 02115

Liver and Biliary Tract Disease in Children, by Daniel Alagille and Micheal Odievre, 364 pp, New York, John Wiley & Sons Inc, 1979.

This concise monograph fills a large gap on the pediatrician's bookshelf. Its pages document the rich clinical experience of Drs Daniel Alagille and Michelle Odievre in conjunction with several collaborators from the pediatric liver research unit at the Hôpital de Bicêtre, Université Paris Sud. The chapters are not individually authored, and the overall quality is assured by multidisciplinary teamwork. The translation from the French by Micheline Ste-Marie of the Pediatric Gastroenterology Unit at Laval University, Quebec, reads remarkably well. However, an occasional awkward word or phase provides more syllables than most Americans would care to pronounce, for example, "syndromatic" vs "nonsyndromatic" versions of a cholestatic disorder initially described by Alagille in 1949. In "nonsyndromatic" patients with isolated cholestasis secondary to paucity of interlobular bile ducts, hepatic disease is severe and may follow prenatal or postnatal infection. Patients with the autosomal dominant, "syndromatic" form have characteristic facies, cardiovascular malformation, vertebral arch defects, and milder chronic liver disease.

The book begins with a critique of various clinical, radiologic, and laboratory methods used in defining pediatric hepatobiliary disease. Indications, limitations, and relative risks are dogmatically and succinctly presented. This forthright style reflects an extensive personal experience with the gamut of invasive and noninvasive procedures. Superb organization and several summary tables provide an amazing amount of information in usable form. Illustrations, particularly the photomicrographs, are of exceptional quality.

Each chapter is amply referenced from both the American and European literature. Since the original French edition antedated the English translation by about one year, more recent literature may be missing. Using the index can be frustrating and disappointing. This may reflect an exaggerated expectation on the part of the reader. This book was never intended to be an encyclopedia of pediatric liver disease, although it is tempting to refer to it as such because of the enormous amount of material contained within these brief chapters. In many instances, not only is the state of the art surveyed but prospective research developments noted as well. Numerous exciting questions are raised and it is to be hoped that answers will be found in future editions. For example, the chapter on the liver in systemic disease points out that the articular symptoms of patients with juvenile rheumatoid arthritis often improve during episodes of viral hepatitis. This phenomenon is not observed in lupus erythematosis. The poorly understood immunologic reactivity of these patients remains to be studied.

It is surprising to learn that the authors have no personal experience with Reye's syndrome. Only eight cases have been reported in France to date. The six-page chapter, therefore, represents a short literature review of the subject. This contrasts sharply with the in-depth analysis of the various forms of hepatitis. Similarly, the chapter on inborn errors of metabolism adequately reviews a 16-year experience at Hôpital d' Enfants de Bicêtre yielding 52 patients with hereditary fructose intolerance and nine patients each with galactosemia and tyrosinemia. The glycogenoses, cystic fibrosis, and Wilson's and Wolman's diseases are also well covered. However, the classification of storage disease fails to mention generalized gangliosidosis (Landing's disease). Severe hepatomegaly occurs in this disorder, and the initial diagnostic suspicion may be aroused during the assessment of the liver biopsy specimen in the appropriate clinical setting. The authors avoid discussing lysosomes and do not show any representative electron micrographs. This may be appropriate for a book intended primarily for clinical use.

Liver pathology associated with total parenteral nutrition is not covered. The inspissated bile syndrome is briefly mentioned and said to have a hemolytic basis. Also, references to bile acid metabolism are essentially absent. It may be particularly interesting to study bile acids in Alagille's disease since Byler's disease, another familial cholestatic syndrome, is associated with high lithocholate levels. In Byler's disease, metabolic cirrhosis may be complicated by hepatoma, and in Alagille's disease, portal fibrosis may be moderate to absent. The interplay between cholestasis and cirrhosis in a variety of metabolic diseases required further clinical and experimental emphasis on the formation and circulation of bile.

As one would expect, there are some discrepancies between the European and the American classifications of hepatobiliary disease. Some pediatric pathologists would classify the hamartomatous fibrocystic lesions of congenital hepatic fibrosis as part of the spectrum of infantile polycystic kidney disease since an occasional pedigree shows autosomal recessive inheritance of both phenotypes. Dr. Benjamin Landing's unitary hypothesis refers to neonatal hepatitis, biliary

atresia, and choledocal cyst as various facets of the same disease process, which he calls infantile obstructive cholangiopathy. As the chapter title indicate, the French workers consider these to be distinct entities. Their major argument is based on the absence of any serologic evidence of antecedent viral infection in patients with extrahepatic biliary atresia and the exceptional occurrence of histologically confirmed intrahepatic and extrahepatic biliary atresia in the same patient.

In his preface, Prof Alagille states this book was conceived 15 years ago. His legacy is worthy of such a long gestation. This marvelous monograph permits the non-French-speaking physician to telescope the bedside teaching rounds and experience derived from one of the world's major centers for pediatric liver disease. Physicians challenged by pediatric hepatic disease will greatly appreciate this book.

Books in Brief

Examination of the Child With Minor Neurological Dysfunction, by Bert C. L. Touwen (141 pp, Philadelphia, JB Lippincott Co, 1979). This how-to-examine text deals with an admittedly difficult area of medical, neurological, and psychological endeavor. The author introduces the subject with a thoughtful review of the enduring debate over minimal brain dysfunction: its definitions, boundaries, and meanings. A discussion of important caveats on the interpretations of neurological signs gives a sense of the turbulence in this complicated field. The neurological examination is described and photographically illustrated in its various components. A standard method of testing is given for each part of the examination, with notations on the recording of performance. A number score system is introduced that codes the performance independently for each component tested. The results are intended to demonstrate a profile of performance and are in no way additive when put on the score sheets. The complexity of the examination and the scoring system suggests that this text would be most useful to those who work in evaluation clinics for such types of disorders, where in-depth study, review, and research might help to add new understanding to this field.

Handbook for Differential Diagnosis of Infectious Diseases, by Johnas A. Shulman, David Schlossberg (280 pp, $13.50, New York, Appleton-Century-Crofts, 1980). This is a purely clinical textbook, designed to be of use to the physician faced with a diagnostic problem. When you must decide what entities to consider in a pneumonia, an "infectious looking" rash, or the interpretation of test findings of the CSF, you will find this well-organized book of value. The section headings deal with "presenting symptom" or "signs," such as diarrhea, jaundice, or splenomegaly. Disease entities subsumed under these categories are discussed briefly, with the stress on the differential aspects of each. The second half of the book consists of charts of the same groups of entities, deals here with the more commonly encountered, treatable conditions, and outlines them in terms of cause, signs, diagnostic studies, and therapy. Of value also are a number of subjects in the appendix. Hematologic changes in various infections, the handling and culture of specimens, and special serologic and skin testing methods are but a few of these useful tools and suggestions. The emphasis is almost exclusively on adult disease states. It should be of great value to house officers, internists, generalists, and those who do a volume of inpatient work. Its small size, soft cover, and affordable price enhance the value of this useful book.

Developmental Disabilities: Etiologies, Manifestations, Diagnoses and Treatments, by Robert J. Thompson, Jr, Aglaia N. O'Quinn (308 pp, $13.95, New York, Oxford University Press, 1979). This book is well researched and well written. The authors, a psychologist and a pediatrician, have done a good review of the literature on a number of important disorders that are included under the term "developmental disorders." For each subject, a historical perspective is given and a resume presented of the clinical manifestations. Infantile autism, for example, is well described, even to the extent of discussing the conflicting views held by various authorities on its cause. References for each chapter are up-to-date and well selected. The causes, manifestations, and diagnostic aspects seem well covered for the most part. Treatment, particularly the concept and implementation of a multidisciplinary approach, seems somewhat scantily handled. By comparison with many thoroughly handled disorders, such as cerebral palsy, subnormality, and seizure disorders, the sensory disorders of speech and hearing seem less thoroughly described. This volume is surely of value to physicians, nurses, and paramedical personnel, but is perhaps overly complex for teachers and those without prior medical training.

The Epileptic in Home, School, and Society: Coping With the Invisible Handicap, by Stephen W. Freeman (285 pp, $14.75, Springfield, Ill, Charles C Thomas Publisher, 1979). This book serves a most important need. It puts together a vast array of information that deals with the world of the epileptic: the medical dimensions of his problem, its causes, treatments, and outlook. The book covers what he can expect to encounter in a world of prejudice, misinformation, and fear as he goes to school, seeks work, and builds a career, and to whom he can turn for help, for answers to hundreds of questions of his rights and his life's prohibitions, for military service, for a driver's license, and for genetic counseling about a family of his own. The author writes well and has assembled an impressive body of facts on these issues. There are good, sensible bits of advice to parents about avoiding overly permissive and solicitous attitudes in child rearing, including advice about giving daily medications to the balky child. The physician might want to loan this book to parents or patients. Nonmedical professionals—teachers, counselors, social workers, therapists of all kinds—should consider having a copy.

Practical Pediatric Dermatology, by William L. Weston ($19.95, Boston, Little Brown & Co, 1979). With the stated purpose of presenting dermatology in an abbreviated form, stressing essentials, this book succeeds admirably. Each disease state is presented in a clear, systematic, orderly style. Two additional elements are

incorporated in the description of each entity: a section titled "Patient Education"; and a suggestion on follow-up visits. Both are seldom mentioned in other dermatology texts. A well-written, comprehensive chapter on dermatopharmacology provides the reader with a sensible, understandable background of general principles of therapy. By reading this section carefully, the clinician should derive much valuable information for his therapeutic methods, so that he is able to apply good-sense management even if he is uncertain on precise cause. Pictures are black-and-white and some lack clarity of detail. However, the expediency of avoiding color photographs keeps the book at a very affordable price. I suspect this will be a popular and useful desk-top reference for most people who find themselves repeatedly puzzled by the rashes of childhood.

A System of Newborn Physical Examination, by John W. Scanlon, Thomas Nelson, Lawrence J. Crylack, Yolande F. Smith (96 pp, $8.95, Baltimore, University Park Press, 1979). How does one go about examining the newborn? This book describes in some detail the elements of the newly born infant: his physical characteristics, the assessment of gestational growth, and neurological and behavioral performance. It pulls together many aspects of neonatal assessment that at present may be widely scattered, such as Dubowitz's scale, Apgar scoring, neurological assessment, the Silverman scoring of respiratory functioning, and normal blood pressure levels. The technique of examination is taken up on a regional basis, for example, as musculoskeletal, abdomen, skin, hair and nails, and the like. At the end, a series of seven cases is presented that illustrates how the findings on examination are synthesized into a meaningful working diagnostic pattern. Appropriate laboratory and other studies are then suggested. This chapter seems very worthwhile, albeit brief. This book seems most appropriate for those who have had limited prior exposure to neonatal infants. It should be used in conjunction with other, more detailed, textbooks that deal with specific entities.

A Vision Fulfilled: The Story of the Childrens Hospital of Winnipeg 1909-1973, by Harry Medovy (156 pp, $12.50, Winnipeg, Manitoba, Canada, Peguis Publishers Ltd, 1979). This is a heartwarming account of a community and its children's hospital, aged 70 this year. The author writes from his 50 years of personal contact, 16 of which were as chief-of-staff. Its founder, Mrs J. R. H. Bond, a nurse, had settled in Winnipeg in 1903. Within several years she had stirred an intense community interest in starting a children's hospital. In 1909, the hospital opened in a converted private house; by 1911 it had moved to a newly erected building. Anecdotes abound in this very personable history. I particularly liked one about the open-sided elevator in the center of the building. It moved so slowly that those walking on the stairway around it could hold their consultations with its trapped occupants. Some of the hospital's renowned medical staff members are remembered in a series of profiles. Its nursing school is prominently reviewed; a complete listing of nurse graduates is given from its first in 1913. Dr Medovy is particularly attentive to giving credit and paying respect to nonmedical supporters of the hospital over its years, obviously a clue to the continued success of the voluntary hospital. The book is nicely illustrated with old photographs. It has a complete index from which the author has modestly excluded himself.

The Clinical Practice of Adolescent Medicine, by Jerome T. Y. Shen (727 pp, $36.50, New York, Appleton-Century-Crofts, 1980). This is a large and comprehensive text that deals exclusively with the adolescent. It is multiauthored by a large number of experts in the field of adolescent medicine and surgery. Largely clinical in direction, there is much difference in styles of presentations; sometimes being very clinical, sometimes quite theoretical. A number of areas receive timely emphasis, such as coronary artery disease, smoking and drug use, sports medicine, and physical fitness. With some clear exceptions, the general emphasis of this text is on disease states and factual material, which seems to be up-to-date and well referenced. There are many physicians who struggle in the care of adolescents and who voice concern about their own ability to cope with adolescent behavior: those devious ways, self-destructive acts, and confused statements. There is little discussion here on how such physicians may understand better and deal more effectively with such behaviors. Coverage of topics is in some areas a bit erratic. Osgood-Schlatter disease is discussed twice. The sex maturity rating scales described in one chapter do not interrelate with those used in the discussion of delayed menarche in the gynecology chapter. Rape is only briefly mentioned, with no advice provided on the sensitive issues of the examination of rape victims. Obesity, described in the text under morbidity as "the most common diagnosis among organic diseases" is handled in a scant two pages. With limitations, this text is a good addition to reference source material on the adolescent.

Health and the Family, edited by Clive Wood (239 pp, $27, New York, Grune & Stratton Inc, 1979). This book contains the proceedings of a symposium held in Cincinnati in May 1978, which was sponsored jointly by the Royal Society of Medicine and the Royal Society of Medicine Foundation. Most of the 27 participants were physicians, 19 of them being from the United States. The subject matter can be grouped into three broad categories: the family itself, the physicians who look after families (or parts of families), and the education of physicians for family care. Underlying and intertwining with most of the discussion is a comparison of two diverse societies, the United States and the United Kingdom. Each of the talks has been carefully edited and referenced. The questions and answers and discussion on each topic are included at the end of each section. All of us who deal with families will find much of great interest in this little volume, irrespective of our viewpoints. One surprising and significant inclusion in the series of topics is the family and the media, which discusses not only the effects of television on family life, but the uses of the media in furthering public education in medicine. This was a timely and interesting conference, one well worth reading. Its presented material seems to have been carefully edited by a tireless staff person who has modestly refrained from any mention of himself apart from the title of "editor."

Have you ruled out cow-milk sensitivity?

The physical symptoms are many and varied: diarrhea, colic, eczema, asthma, vomiting, bronchitis, rhinitis. They can be coupled with behavioral symptoms: repeated refusal of the nursing bottle . . . general fussiness.[1-3]

Alone or together, the manifestations of milk sensitivity are an unnecessary burden for the infant . . . and parents. More important, if unchecked the allergic syndromes can lead to failure to thrive and other serious health problems.[4]

With Isomil® Soy Protein Formula you can avoid the symptoms of milk sensitivity and help confirm your initial diagnosis.

Moreover, Isomil promotes normal growth.[2,5] It looks like milk, it pours like milk and has a pleasant aroma, which help insure acceptability. Unlike milk, Isomil is lactose free. It avoids the possibility of prolonged or recurring diarrhea caused by lactose intolerance.

Consider the possibility of milk sensitivity when associated symptoms are presented. "A high index of suspicion" is essential to its prompt detection.[2,6]

PAIN GONE

while the antibiotic gets going

An effective adjuvant to systemic antibiotic treatment, AURALGAN promptly relieves the pain and reduces the inflammation of acute otitis media, while the antibiotic of choice fights the infection.

AURALGAN contains the topical analgesic action of benzocaine and antipyrine plus glycerin dehydrated...a decongestant so hygroscopic that it "blots up" excess moisture through the tympanic membrane, for relief of pressure and pain in the middle ear.

BRIEF SUMMARY
(For full prescribing information, see package circular.)
AURALGAN® Otic Solution
Each ml contains:
Antipyrine . . . . . 54.0 mg
Benzocaine . . . . . 14.0 mg
Glycerin dehydrated q.s. to . . . . . 1.0 ml
(contains not more than 1.0% moisture) (also contains oxyquinoline sulfate)
INDICATIONS: *Acute otitis media of various etiologies*
—prompt relief of pain and reduction of inflammation in the congestive and serous stages
—adjuvant therapy during systemic antibiotic administration for resolution of the infection
CONTRAINDICATIONS: Hypersensitivity to any of the components or substances related to them./ In the presence of spontaneous perforation or discharge.
DOSAGE AND ADMINISTRATION: *Acute otitis media:* Instill AURALGAN, permitting the solution to run along the wall of the canal until it is filled. Avoid touching the ear with dropper. Then moisten a cotton pledget with AURALGAN and insert into meatus. Repeat every one to two hours until pain and congestion are relieved.
HOW SUPPLIED: No.1000—AURALGAN® Otic Solution, in package containing 15 ml (½ fl oz) bottle with separate dropper-screw cap attachment.

...in acute otitis media

Auralgan®

Carnation Evaporated Milk formulas have been raising strong, healthy babies since 1899—delivering the good, sound, natural nutrition newborns and infants thrive on. You see, Carnation Evaporated Milk has naturally-occurring protein with all other nutrients intact. You indicate vitamins, iron, and carbohydrates to meet each baby's needs. Importantly, bottle for bottle, a whole formula made with Carnation Evaporated Milk still costs new mothers less than any proprietary formula. Carnation Evaporated Milk... for four generations. The babies under your care will thrive on it, too.

FREE! Send for your sample copy of the informative patient-oriented booklet: "Preparing Your Baby's Formula." Mail to: Carnation Company, P.O. Box 550, Dept. OB, Pico Rivera, CA 90665.

Designate one author as correspondent and provide his/her address and telephone number. Manuscripts are received with the understanding that they are not under simultaneous consideration by another publication. Accepted manuscripts become the permanent property of the *American Journal of Diseases of Children* and may not be published elsewhere without permission from the publisher (AMA).

In view of the provisions of *The Copyright Revision Act of 1976*, effective Jan 1, 1978, the author(s) of manuscripts, letters to the editor, and book reviews accepted for publication in the JOURNAL will be required to sign and date the following statement: "In consideration of the AMA taking action in reviewing and editing my/our submission, the author(s) undersigned hereby transfers, assigns, or otherwise conveys all copyright ownership to the AMA in the event that such work is published by the AMA."

Manuscript Preparation.—All the elements of a manuscript must be submitted in **triplicate, double-spaced throughout**. Use heavy-duty white bond paper, 21.6 × 27.9 cm, and 4-cm margins. If a word processor is used, do not justify lines. The style of writing should conform to proper English usage and syntax. All measurements are to be in metric units, temperatures in Centigrade.

All accepted manuscripts are subject to copy editing. The corresponding author will receive an edited typescript and layout for approval. Forms for ordering reprints are included with the edited typescript. Proofs will be sent for approval if requested by the author and if printing deadlines permit. The author is responsible for all statements in his/her work, including changes made by the copy editor.

Titles.—Titles should be short, specific, and clear. They should not exceed 42 characters per line, including punctuation and spaces, and be limited to two lines. The title page should include the full names and academic affiliations of all authors, the address to which requests for reprints should be sent, and, if the manuscript was presented at a meeting, the name of the organization, place, and date on which it was read.

Abstract.—Provide an abstract (135-word maximum) of the article, including statement of the problem, method of study, results, and conclusions. The abstract replaces the summary.

Informed Consent.—Manuscripts reporting the results of experimental investigations on humans must include a statement to the effect that informed consent was obtained from the parents or guardians after the nature of the procedure(s) had been fully explained.

Clinical Memoranda.—Brief accounts of interesting observations and clinical situations. Limited to 800 words plus one table or illustration; abstract unnecessary. Submit in triplicate, double-spaced. Copyright assignment required.

Letters to the Editor.—Correspondence pertaining to material published in the JOURNAL. Limit 500 words. Submit in triplicate, double-spaced, and clearly marked "For publication." Copyright assignment required.

References.—List in order of their appearance in the text, and type double-spaced, in the following manner:

1. Applebaum MM, Thaler MM: Reye syndrome without initial hepatic involvement. *Am J Dis Child* 1977; 131:295-296.
2. Koller LR: *Ultraviolet Radiation*, ed 2. New York, John Wiley & Sons, 1965, 141-160.
3. Daughaday WH: The adenohypophysis, in Williams RH (ed): *Textbook of Endocrinology*, ed 5. Philadelphia, WB Saunders, 1974: 31-79.

Do not include unpublished data, personal communications, or manuscripts "in preparation" or "submitted" in the list of references. Such material, if essential, may be incorporated in the body of the article.

Illustrations.—Submit only high-contrast glossy prints in triplicate, unmounted and untrimmed. Preferred size is 12.7 × 17.3 cm (5 × 7 in). Figure number, name of first author, and arrow indicating "top" should be typed on a gummed label and affixed to the back of each illustration. Lettering must be legible after reduction to column size. Magnification and stain should be provided for histologic sections.

For illustrations in full color submit 35-mm, positive color transparencies, mounted in cardboard and carefully packaged. Do not submit glass-mounted transparencies; do not submit color prints. The fee is $275 for up to six square-finished color illustrations that can be arranged on one page. A letter of intent to pay the fee must accompany submission.

Legends.—Legends for illustrations should be typed double-spaced, beginning on a separate sheet of paper (40-word maximum for each).

Acknowledgments.—Illustrations and tables from other publications must be suitably acknowledged, and accompanied by written permission from publisher and author.

Photographic Consents.—A signed statement of consent from both parents (or guardian) or the persons involved must accompany all photographs of patients in which a possibility of identification exists. It is not sufficient to cover the eyes to mask identity.

Tables.—Each table should be typed double-spaced, including all headings, on a separate sheet of 21.6 × 27.9 cm paper. If a table must be continued, use a second sheet and repeat all heads. Each table must have a title.

Uniform Requirements.—Further details on manuscript preparation are given in the document *Uniform Requirements for Manuscripts Submitted to Biomedical Journals* prepared by the International Steering Committee of Medical Editors. Reprints of this document are available by directing requests to this journal: Scientific Publications, 535 N Dearborn St, Chicago, IL 60610.

NOW PETER

Attention Deficit Disorders* under control...
His natural abilities are coming through

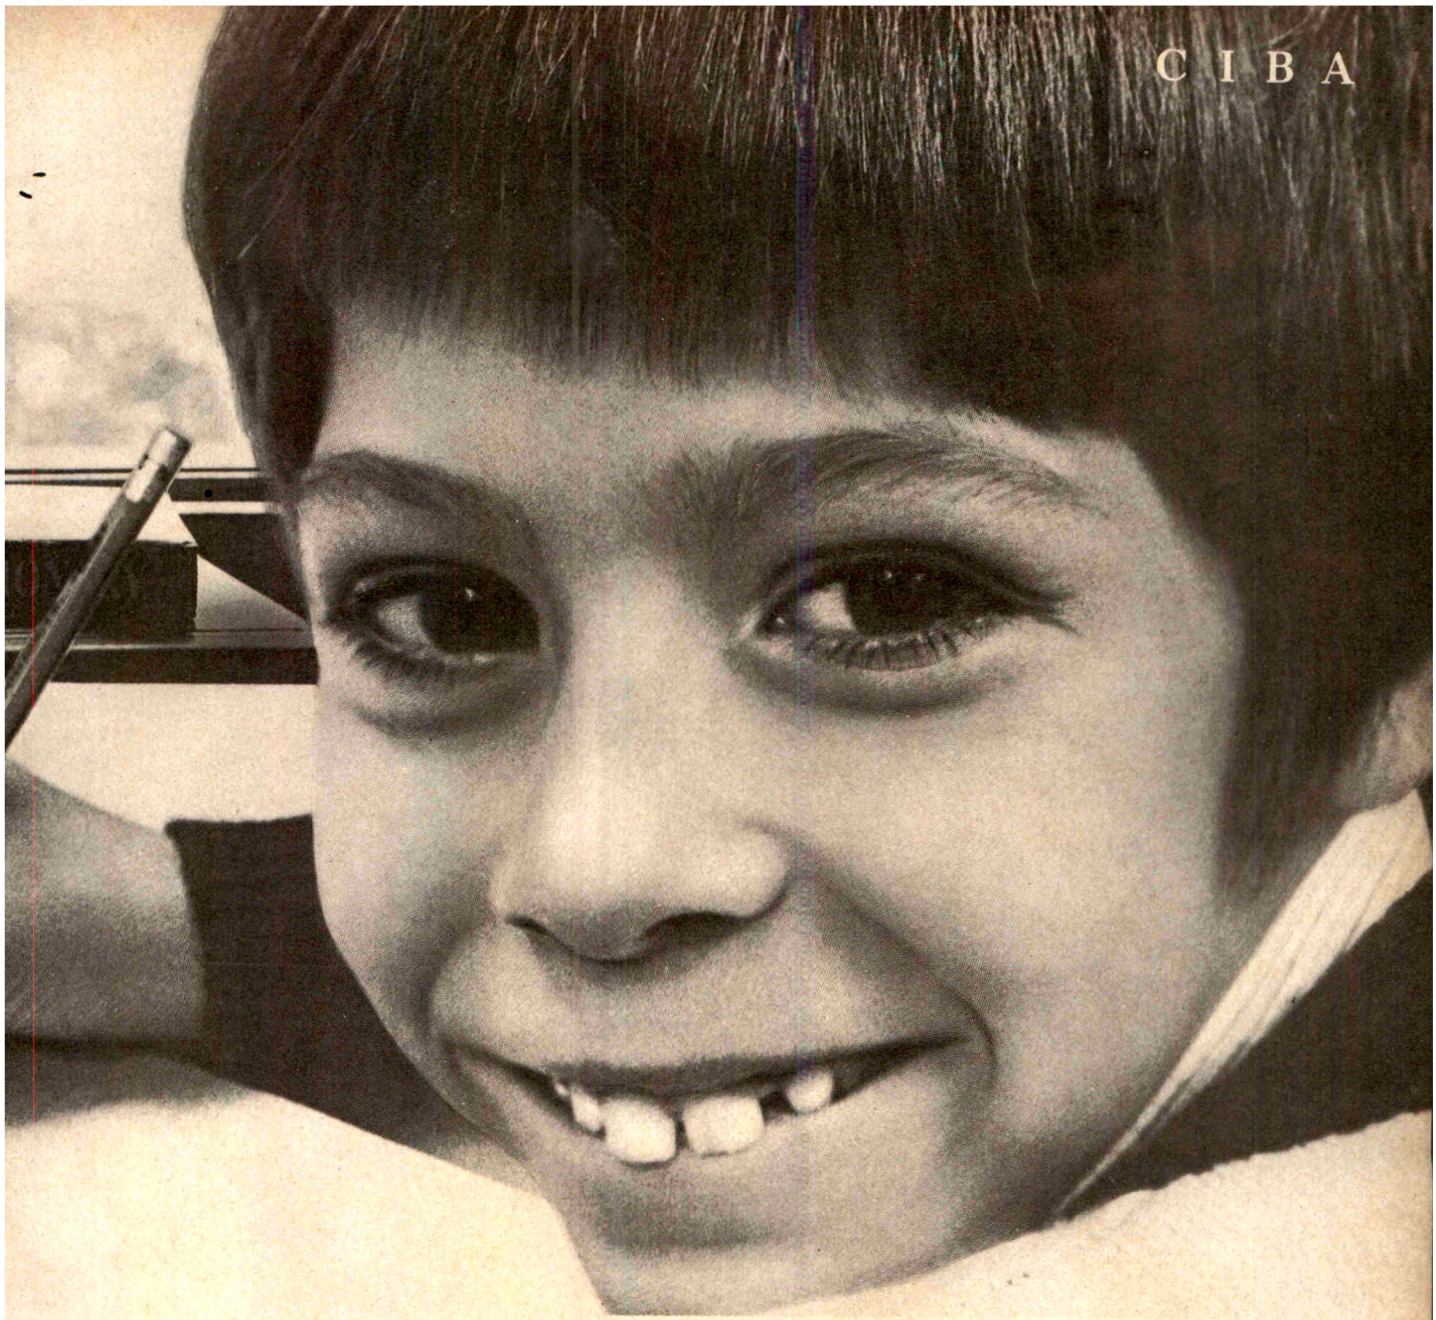
Now Peter's enjoying more things at play as well as in school. He works better with his teacher and classmates... likes doing things with his dad... gets more natural pleasure out of family and friends.

Now that his concentration is improved, his natural abilities are coming through. He's functioning better. Under a well-integrated program of treatment for Attention Deficit Disorders (ADD), hyperactivity and impulsiveness are markedly reduced.

Ritalin (methylphenidate) can be a vital part of his regimen. With adjunctive use of Ritalin, many ADD children are better able to control hyperkinetic behavior —act in a more natural and appropriate manner.

A 20-year record of proven efficacy

Over the years, Ritalin has become an established choice for pharmacotherapy of ADD. In a report by the



BEHAVES MORE NATURALLY.

National Council on Child Health,[1] Ritalin was described as among the most effective and best-documented agents for stimulant therapy in hyperkinetic children.

Reduces hyperactivity, impulsive behavior

Ritalin has a well-documented record of success in relieving the dominant symptoms of ADD. As it reduces distractibility, disorganized behavior and hyperactivity, improved school performance usually results,[2,3] as well as better peer interaction.[2]

Generally well tolerated

Although side effects may occur with Ritalin, they are generally not serious. During prolonged therapy, anorexia, weight loss, and insomnia are among the most frequently encountered adverse reactions. (See Adverse Reactions section of the prescribing information.) Even though most children require long-term treatment, there is little evidence of habituation.[1]

Therapy with Ritalin should be considered only after a medical diagnosis of ADD has been confirmed. Dosage can usually be interrupted during weekends and vacations. In some cases, these drug holidays reveal "stabilization" in the child's behavior without medication. They may permit a reduction in dosage and eventual discontinuation of drug therapy if warranted.

*Attention Deficit Disorders: new designation by the American Psychiatric Association; formerly called Minimal Brain Dysfunction (MBD) or Hyperkinetic Syndrome.

Ritalin . . . only when medication is indicated for Attention Deficit Disorders

Ritalin®
(methylphenidate)
as adjunctive therapy for ADD

Ritalin® C II (methylphenidate)

Only when medication is indicated

Ritalin® hydrochloride (methylphenidate hydrochloride USP) C II

TABLETS

INDICATIONS

Attention Deficit Disorders (previously known as Minimal Brain Dysfunction in Children). Other terms being used to describe the behavioral syndrome below include: Hyperkinetic Child Syndrome, Minimal Brain Damage, Minimal Cerebral Dysfunction, Minor Cerebral Dysfunction.

Ritalin is indicated as an integral part of a total treatment program which typically includes other remedial measures (psychological, educational, social) for a stabilizing effect in children with a behavioral syndrome characterized by the following group of developmentally inappropriate symptoms: moderate-to-severe distractibility, short attention span, hyperactivity, emotional lability, and impulsivity. The diagnosis of this syndrome should not be made with finality when these symptoms are only of comparatively recent origin. Nonlocalizing (soft) neurological signs, learning disability, and abnormal EEG may or may not be present, and a diagnosis of central nervous system dysfunction may or may not be warranted.

Special Diagnostic Considerations

Specific etiology of this syndrome is unknown, and there is no single diagnostic test. Adequate diagnosis requires the use not only of medical but of special psychological, educational, and social resources.

Characteristics commonly reported include: chronic history of short attention span, distractibility, emotional lability, impulsivity, and moderate-to-severe hyperactivity; minor neurological signs and abnormal EEG. Learning may or may not be impaired. The diagnosis must be based upon a complete history and evaluation of the child and not solely on the presence of one or more of these characteristics.

Drug treatment is not indicated for all children with this syndrome. Stimulants are not intended for use in the child who exhibits symptoms secondary to environmental factors and/or primary psychiatric disorders, including psychosis. Appropriate educational placement is essential and psychosocial intervention is generally necessary. When remedial measures alone are insufficient, the decision to prescribe stimulant medication will depend upon the physician's assessment of the chronicity and severity of the child's symptoms.

CONTRAINDICATIONS

Marked anxiety, tension, and agitation are contraindications to Ritalin, since the drug may aggravate these symptoms. Ritalin is contraindicated also in patients known to be hypersensitive to the drug and in patients with glaucoma.

WARNINGS

Ritalin should not be used in children under six years, since safety and efficacy in this age group have not been established.

Sufficient data on safety and efficacy of long-term use of Ritalin in children are not yet available. Although a causal relationship has not been established, suppression of growth (*ie*, weight gain, and/or height) has been reported with the long-term use of stimulants in children. Therefore, patients requiring long-term therapy should be carefully monitored.

Ritalin should not be used for severe depression of either exogenous or endogenous origin. Clinical experience suggests that in psychotic children, administration of Ritalin may exacerbate symptoms of behavior disturbance and thought disorder.

Ritalin should not be used for the prevention or treatment of normal fatigue states.

There is some clinical evidence that Ritalin may lower the convulsive threshold in patients with prior history of seizures, with prior EEG abnormalities in absence of seizures, and, very rarely, in absence of history of seizures and no prior EEG evidence of seizures. Safe concomitant use of anticonvulsants and Ritalin has not been established. In the presence of seizures, the drug should be discontinued.

Use cautiously in patients with hypertension. Blood pressure should be monitored at appropriate intervals in all patients taking Ritalin, especially those with hypertension.

Symptoms of visual disturbances have been encountered in rare cases. Difficulties with accommodation and blurring of vision have been reported.

Drug Interactions

Ritalin may decrease the hypotensive effect of guanethidine. Use cautiously with pressor agents and MAO inhibitors.

Human pharmacologic studies have shown that Ritalin may inhibit the metabolism of coumarin anticoagulants, anticonvulsants (phenobarbital, diphenylhydantoin, primidone), phenylbutazone, and tricyclic antidepressants (imipramine, desipramine). Downward dosage adjustments of these drugs may be required when given concomitantly with Ritalin.

Usage in Pregnancy

Adequate animal reproduction studies to establish safe use of Ritalin during pregnancy have not been conducted. Therefore, until more information is available, Ritalin should not be prescribed for women of childbearing age unless, in the opinion of the physician, the potential benefits outweigh the possible risks.

Drug Dependence

Ritalin should be given cautiously to emotionally unstable patients, such as those with a history of drug dependence or alcoholism, because such patients may increase dosage on their own initiative.

Chronically abusive use can lead to marked tolerance and psychic dependence with varying degrees of abnormal behavior. Frank psychotic episodes can occur, especially with parenteral abuse. Careful supervision is required during drug withdrawal, since severe depression as well as the effects of chronic overactivity can be unmasked. Long-term follow-up may be required because of the patient's basic personality disturbances.

PRECAUTIONS

Patients with an element of agitation may react adversely; discontinue therapy if necessary.

Periodic CBC, differential, and platelet counts are advised during prolonged therapy.

Drug treatment is not indicated in all cases of this behavioral syndrome and should be considered only in light of the complete history and evaluation of the child. The decision to prescribe Ritalin should depend on the physician's assessment of the chronicity and severity of the child's symptoms and their appropriateness for his/her age. Prescription should not depend solely on the presence of one or more of the behavioral characteristics.

When these symptoms are associated with acute stress reactions, treatment with Ritalin is usually not indicated.

Long-term effects of Ritalin in children have not been well established.

The Ritalin tablets (5 and 20 mg) contain FD&C Yellow No. 5 (tartrazine) which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals. Although the overall incidence of FD&C Yellow No. 5 (tartrazine) sensitivity in the general population is low, it is frequently seen in patients who also have aspirin hypersensitivity.

ADVERSE REACTIONS

Nervousness and insomnia are the most common adverse reactions but are usually controlled by reducing dosage and omitting the drug in the afternoon or evening. Other reactions include hypersensitivity (including skin rash, urticaria, fever, arthralgia, exfoliative dermatitis, erythema multiforme with histopathological findings of necrotizing vasculitis, and thrombocytopenic purpura); anorexia; nausea; dizziness; palpitations; headache; dyskinesia; drowsiness; blood pressure and pulse changes, both up and down; tachycardia; angina; cardiac arrhythmia; abdominal pain; weight loss during prolonged therapy. Toxic psychosis has been reported. Although a definite causal relationship has not been established, the following have been reported in patients taking this drug: leukopenia and/or anemia; a few instances of scalp hair loss.

In children, loss of appetite, abdominal pain, weight loss during prolonged therapy, insomnia, and tachycardia may occur more frequently; however, any of the other adverse reactions listed above may also occur.

DOSAGE AND ADMINISTRATION

Children (6 years and over)

Start with small doses (*eg*, 5 mg before breakfast and lunch) with gradual increments of 5 to 10 mg weekly. Daily dosage above 60 mg is not recommended. If improvement is not observed after appropriate dosage adjustment over a one-month period, the drug should be discontinued.

If paradoxical aggravation of symptoms or other adverse effects occur, reduce dosage, or, if necessary, discontinue the drug.

Where possible, drug administration should be interrupted occasionally to determine if there is a recurrence of behavioral symptoms sufficient to require continued therapy. Improvement may be sustained when the drug is either temporarily or permanently discontinued.

Drug treatment should not and need not be indefinite and usually may be discontinued after puberty.

HOW SUPPLIED

Tablets, 20 mg (peach, scored); bottles of 100 and 1000.

Tablets, 10 mg (pale green, scored); bottles of 100, 500, 1000 and Accu-Pak® blister units of 100.

Tablets, 5 mg (pale yellow); bottles of 100, 500 and 1000.

Dispense in tight, light-resistant container (USP).

665382 C80-14 (1/80)

Consult complete product literature before prescribing.

Filling a need since 1927

"In offering Similac to the Medical Profession we do so with the thought in mind that breast milk is nature's food for the infant, but as many infants are deprived of their natural food, either wholly or in part, some form of nourishment must be substituted, and Similac is offered as this substitute."

The above statement appeared in medical journals in the announcement of the introduction of Similac® Infant Formulas in 1927. Today, as then, we continue to recognize and support breast-feeding as the ideal feeding for infants.

Over the years, Ross Laboratories has promoted and supported breast-feeding by providing health professionals with service materials and patient counseling literature.

However, it should be recognized that not all infants will be breast-fed throughout the first year of life. Similac With Iron is offered for your consideration as a better alternative than cow milk if the mother discontinues breast-feeding early, if a supplement to breast-feeding is needed, or if breast-feeding is not adopted.

Our objective is to provide an appropriate infant feeding for those instances when an infant does not receive breast milk. We are proud of Similac Infant Formulas and are proud to have filled a need for high quality infant feeding for over 50 years.

a chance for a better life with Depakene®
Valproic Acid

For your patients with mixed seizures including absence, or pure absence

Effective seizure control[1] without cosmetic disfigurement

In 28 studies of patients with mixed grand mal and absence, 76% of all patients gained significant improvement; over one-third became seizure-free. In 60 studies involving pure absence, 86% of patients were improved; half became seizure-free.

While serious side effects, including fatal hepatitis, have occurred, the most common side effect with Depakene is G.I. upset, which usually responds to temporary dosage reduction. Problem sedation is not common and cosmetic stigmata such as gum hypertrophy and hirsutism do not occur.

A widely useful anticonvulsant

Depakene is indicated as sole or adjunctive therapy in both simple and complex absence seizures. It is also indicated for adjunctive treatment of patients with multiple seizure types which include absence. Clinical response has been especially noteworthy among patients with generalized tonic-clonic attacks, or with minor motor seizures (e.g., myoclonic movements, akinetic seizures), where combined with absence.

Offering your patients a chance for a better life

Sustained freedom from seizures can mean a drivers license, an active social schedule, involvement in athletic competition—a better life for your patient.

1. Worldwide studies of Depakene experience (Data refer only to grand mal and/or absence seizures. Since each type was evaluated separately, some patients appear in both groups. Though most of these studies were uncontrolled and had widely differing protocols, their collective data clearly support efficacy of the drug).

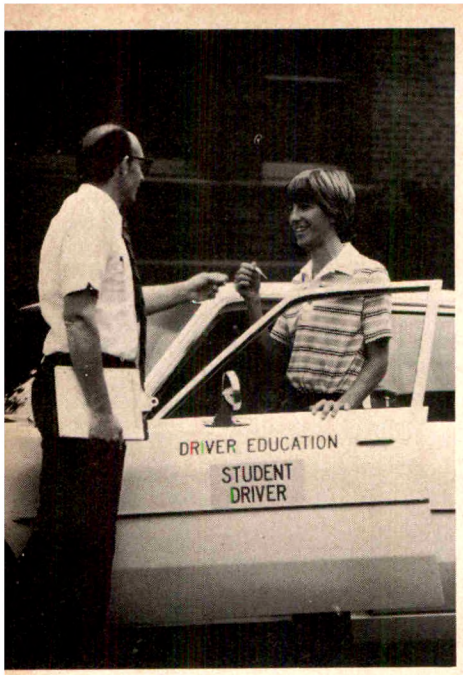
See overleaf for prescribing information

Abbott Laboratories,
North Chicago, Illinois 60064

0013326R2

Depakene®
Valproic Acid Capsules 250 mg
250 mg/5 ml syrup

Depakene®
Valproic Acid



Offering a chance for a better life for your patients with mixed seizures including absence, or pure absence

PRESCRIBING INFORMATION

INDICATIONS: DEPAKENE (valproic acid) is indicated for use as sole and adjunctive therapy in the treatment of simple and complex absence seizures, including petit mal. DEPAKENE may also be used adjunctively in patients with multiple seizure types which include absence seizures.

In accordance with the International Classification of Seizures, simple absence is defined as very brief clouding of the sensorium or loss of consciousness (lasting usually 2-15 seconds), accompanied by certain generalized epileptic discharges without other detectable clinical signs. Complex absence is the term used when other signs are also present.

CONTRAINDICATIONS: DEPAKENE (valproic acid) is contraindicated in patients with known hypersensitivity to the drug.

WARNINGS: Hepatic failure resulting in fatalities has occurred in patients receiving DEPAKENE. These incidences usually have occurred during the first six months of treatment with DEPAKENE. Liver function tests should be performed prior to therapy and at frequent intervals thereafter. Caution should be observed when administering DEPAKENE to patients with pre-existing hepatic disease.

The drug should be discontinued immediately in the presence of significant hepatic dysfunction, suspected or apparent. The frequency of adverse effects (particularly elevated liver enzymes) may increase with increasing dose. Therefore, the benefit gained by increased seizure control by increasing the dosage must be weighed against the increased incidence of adverse effects sometimes seen at higher dosages.

Usage in Pregnancy: THE EFFECTS OF DEPAKENE IN HUMAN PREGNANCY ARE UNKNOWN. ANIMAL STUDIES HAVE DEMONSTRATED TERATOGENICITY.

Studies in rats demonstrated placental transfer of the drug. Doses greater than 65 mg/kg/day given to pregnant rats and mice produced skeletal abnormalities in the offspring, primarily involving ribs and vertebrae; doses greater than 150 mg/kg/day given to pregnant rabbits produced fetal resorptions and (primarily) soft-tissue abnormalities in the offspring. In rats a dose-related delay in the onset of parturition was noted. Postnatal growth and survival of the progeny were adversely affected, particularly when drug administration spanned the entire gestation and early lactation period.

THERE ARE MULTIPLE REPORTS IN THE CLINICAL LITERATURE WHICH INDICATE THAT THE USE OF ANTICONVULSANT DRUGS DURING PREGNANCY RESULTS IN AN INCREASED INCIDENCE OF BIRTH DEFECTS IN THE OFFSPRING. ALTHOUGH DATA ARE MORE EXTENSIVE WITH RESPECT TO TRIMETHADIONE, PARAMETHADIONE, PHENYTOIN, AND PHENOBARBITAL, REPORTS INDICATE A POSSIBLE SIMILAR ASSOCIATION WITH THE USE OF OTHER ANTICONVULSANT DRUGS. THEREFORE, ANTICONVULSANT DRUGS SHOULD BE ADMINISTERED TO WOMEN OF CHILDBEARING POTENTIAL ONLY IF THEY ARE CLEARLY SHOWN TO BE ESSENTIAL IN THE MANAGEMENT OF THEIR SEIZURES.

Anticonvulsant drugs should not be discontinued in patients in whom the drug is administered to prevent major seizures because of the strong possibility of precipitating status epilepticus with attendant hypoxia and threat to life. In individual cases where the severity and frequency of the seizure disorder are such that the removal of medication does not pose a serious threat to the patient, discontinuation of the drug may be considered prior to and during pregnancy, although it cannot be said with any confidence that even minor seizures do not pose some hazard to the developing embryo or fetus.

The prescribing physician will wish to weigh these considerations in treating or counseling epileptic women of childbearing potential.

PRECAUTIONS: *Hepatic dysfunction:* See WARNINGS.

General: Because of reports of thrombocytopenia and platelet aggregation dysfunction, platelet counts and bleeding time determination are recommended before initiating therapy and at periodic intervals. It is recommended that patients receiving DEPAKENE be monitored for platelet count prior to planned surgery. Clinical evidence of hemorrhage, bruising or a disorder of hemostasis/coagulation is an indication for reduction of DEPAKENE dosage or withdrawal of therapy pending investigation.

Since DEPAKENE (valproic acid) may interact with concurrently administered anticonvulsant drugs, periodic serum level determinations of concomitant anticonvulsant drugs are recommended during the early course of therapy. (See Drug Interactions).

DEPAKENE is partially eliminated in the urine as a keto-metabolite which may lead to a false interpretation of the urine ketone test.

Information For Patients: Since DEPAKENE may produce CNS depression, especially when combined with another CNS depressant (e.g., alcohol), patients should be advised not to engage in hazardous occupations, such as driving an automobile or operating dangerous machinery, until it is known that they do not become drowsy from the drug.

Drug Interactions: DEPAKENE may potentiate the CNS depressant activity of alcohol.

THERE IS EVIDENCE THAT DEPAKENE MAY CAUSE AN INCREASE IN SERUM PHENOBARBITAL LEVELS, ALTHOUGH THE MECHANISM OF THE INTERACTION IS UNKNOWN. ALL PATIENTS RECEIVING CONCOMITANT BARBITURATE THERAPY SHOULD BE CLOSELY MONITORED FOR NEUROLOGICAL TOXICITY, SERUM BARBITURATE DRUG LEVELS OBTAINED, IF POSSIBLE, AND THE BARBITURATE DOSAGE DECREASED, IF APPROPRIATE.

Primidone is metabolized into a barbiturate and, therefore, may also be involved in a similar or identical interaction.

THERE IS CONFLICTING EVIDENCE REGARDING THE INTERACTION OF DEPAKENE WITH PHENYTOIN. IT IS NOT KNOWN IF THERE IS A CHANGE IN UNBOUND (FREE) PHENYTOIN SERUM CONCENTRATIONS. THE DOSAGE OF PHENYTOIN SHOULD BE ADJUSTED AS REQUIRED BY THE CLINICAL SITUATION.

THE CONCOMITANT USE OF VALPROIC ACID AND CLONAZEPAM MAY PRODUCE ABSENCE STATUS.

Caution is recommended when DEPAKENE (valproic acid) is administered with drugs affecting coagulation, e.g., aspirin and warfarin. (See ADVERSE REACTIONS).

Carcinogenesis, Mutagenesis: There has been insufficient study of the drug in animals to determine whether it has carcinogenic potential. Carcinogenicity studies in rats and mice are currently in progress.

Mutagenesis studies on DEPAKENE have been performed using bacterial and mammalian systems. These studies have provided no evidence of a mutagenic potential for DEPAKENE.

Pregnancy: See WARNINGS.

Nursing Mothers: DEPAKENE is excreted in breast milk. It is not known what effect this would have on a nursing infant. As a general rule, nursing should not be undertaken while a patient is receiving DEPAKENE.

Fertility: Chronic toxicity studies in juvenile and adult rats and dogs demonstrated reduced spermatogenesis and testicular atrophy at doses greater than 200 mg/kg/day in rats and greater than 90 mg/kg/day in dogs. Segment I fertility studies in rats have shown doses up to 350 mg/kg/day for 60 days to have no effect on fertility. THE EFFECT OF DEPAKENE (VALPROIC ACID) ON THE DEVELOPMENT OF THE TESTES AND ON SPERM PRODUCTION AND FERTILITY IN HUMANS IS UNKNOWN.

ADVERSE REACTIONS: Since DEPAKENE (valproic acid) has usually been used with other anticonvulsant drugs, it is not possible, in most cases, to determine whether the following adverse reactions can be ascribed to DEPAKENE alone, or the combination of drugs.

Gastrointestinal: The most commonly reported side effects at the initiation of therapy are nausea, vomiting and indigestion. These effects are usually transient and rarely require discontinuation of therapy. Diarrhea, abdominal cramps and constipation have been reported. Both anorexia with some weight loss and increased appetite with weight gain have also been reported.

CNS Effects: Sedative effects have been noted in patients receiving valproic acid alone but are found most often in patients receiving combination therapy. Sedation usually disappears upon reduction of other anticonvulsant medication. Ataxia, headache, nystagmus, diplopia, asterixis, "spots before eyes", tremor, dysarthria, dizziness, and incoordination have rarely been noted. Rare cases of coma have been noted in patients also on phenobarbital.

Dermatologic: Transient increases in hair loss have been observed. Skin rash and petechiae have rarely been noted.

Psychiatric: Emotional upset, depression, psychosis, aggression, hyperactivity and behavioral deterioration have been reported.

Musculoskeletal: Weakness has been reported.

Hematopoietic: Thrombocytopenia has been reported. Valproic acid inhibits the secondary phase of platelet aggregation. (See DRUG INTERACTIONS). This may be reflected in altered bleeding time. Bruising, hematoma formation and frank hemorrhage have been reported. Relative lymphocytosis and hypofibrinogenemia have been noted. Leukopenia and eosinophilia have also been reported.

Hepatic: Increases in serum alkaline phosphatase and elevations of serum glutamic oxaloacetic transaminase (SGOT) have been noted. Elevation of SGOT may be dose related. Elevations of SGPT and LDH have been noted less frequently. Isolated cases of severe hepatotoxicity have been reported but do not appear dose related. (See WARNINGS).

OVERDOSAGE: A single case of overdosage with valproic acid has been reported. After ingesting 36 grams in combination with phenobarbital and phenytoin, the patient presented in deep coma. An electroencephalogram recorded diffuse slowing, compatible with the state of consciousness. The patient made an uneventful recovery.

Since DEPAKENE is absorbed very rapidly, gastric lavage may be of limited value. General supportive measures should be applied with particular attention being given to the maintenance of adequate urinary output.

DOSAGE AND ADMINISTRATION: DEPAKENE (valproic acid) is administered orally. The recommended initial dose is 15 mg/kg/day, increasing at one week intervals by 5 to 10 mg/kg/day, until seizures are controlled or side effects preclude further increases. The maximum recommended dosage is 60 mg/kg/day. If the total daily dose exceeds 250 mg, it should be given in a divided regimen.

The frequency of adverse effects (particularly elevated liver enzymes) may increase with increasing dose. Therefore, the benefit gained by increased seizure control by increased dosage must be weighed against the increased incidence of adverse effects sometimes seen at higher doses.

The following table is a guide for the initial daily dose of DEPAKENE (valproic acid) (15 mg/kg/day):

Weight (kg)	Weight (lb)	Total Daily Dose (mg)	Number of Capsules or Teaspoonfuls of Syrup Dose 1	Dose 2	Dose 3
10 - 24.9	22 - 54.9	250	0	0	1
25 - 39.9	55 - 87.9	500	1	0	1
40 - 59.9	88 - 131.9	750	1	1	1
60 - 74.9	132 - 164.9	1,000	1	1	2
75 - 89.9	165 - 197.9	1,250	2	1	2

A good correlation has not been established between daily dose, serum level and therapeutic effect, however, therapeutic serum levels for most patients will range from 50 to 100 mcg/ml. Occasional patients may be controlled with serum levels lower or higher than this range.

As the DEPAKENE dosage is titrated upward, blood levels of phenobarbital and/or phenytoin may be affected. (See PRECAUTIONS).

Patients who experience G.I. irritation may benefit from administration of the drug with food or by slowly building up the dose from an initial low level.

THE CAPSULES SHOULD BE SWALLOWED WITHOUT CHEWING TO AVOID LOCAL IRRITATION OF THE MOUTH AND THROAT.

HOW SUPPLIED: DEPAKENE (valproic acid) is available as orange-colored soft gelatin capsules of 250 mg valproic acid in bottles of 100 capsules (**NDC** 0074-5681-13), and as a red syrup containing the equivalent of 250 mg valproic acid per 5 ml as the sodium salt in bottles of 16 ounces (**NDC** 0074-5682-16).

Sleep Hypoxemia in Patients With Cystic Fibrosis

Two important issues are involved in the demonstration of sleep hypoxemia in patients with cystic fibrosis. First, the degrees of arterial oxygen desaturation presently shown by Francis et al (see p 734) may be great enough to accelerate the progress of cor pulmonale. Second, disturbance of the normal sleep pattern is a problem recognized by patients with advanced pulmonary disease. It certainly worsens their quality of life and may well hasten the course of the disease itself.

Relationships between sleep state and breathing are now studied with great interest by researchers in respiratory physiology, neurophysiology, and anesthesiology. New techniques allow meaningful descriptions of sleep state, activity of respiratory muscles, mechanics of breathing, and changes in arterial blood gas levels. However, the pertinent questions arose from clinical observations. Adults with severe chronic obstructive pulmonary disease have long been known to suffer reversal of the normal sleep pattern; they have increasing wakefulness at night and somnolence during the day as their hypoxemia worsens.[1] Some respiratory physiologists involved in the care of such patients have resided at high altitudes and have experienced sleep disturbance themselves. Subsequent studies of normal subjects sleeping at high altitudes have shown profound oxygen desaturation associated with periodic breathing, partly uncovering the cause of mountain sickness.[2] Pediatricians have observed that children with the syndrome of upper airway obstruction and cor pulmonale often fail to provide convincing evidence of obstruction while awake. Now we know that apparently normal middle-aged men may suffer bouts of arterial oxygen desaturation with upper airway obstruction while asleep[3] and that muscular control of upper airway patency is defective in certain sleep states.[4] Obesity has long been implicated as a cause of hypoventilation during sleep and we now recognize that obese persons may breathe at very low lung volumes in the supine position, predisposing to airway closure and increasing the work of breathing.

Patients with cystic fibrosis are rarely obese and do not show propensities for either upper airway obstruction or periodic breathing while asleep. Why are they predisposed to sleep hypoxemia? In some stages of rapid eye movement (REM) sleep, intercostal muscle tone is greatly diminished and central respiratory drive irregular.[5] Francis et al found slight hemoglobin desaturation in their group of young adult controls during REM sleep, but more severe desaturation in their patients. In a recent study of young adults with cystic fibrosis, Stokes et al (see p 741) detected the uncoupling of abdominothoracic motion that would be expected from a large decrease in intercostal muscle tone during REM sleep. These events were associated with significant arterial oxygen desaturation. Therefore, it seems that a normal change in control of respiration, rather than one unique to the patients, decreases lung capacity during sleep. In young, normal adults, such a decrease in lung capacity has little or no effect on gas exchange. Since most teenagers and young adults with cystic fibrosis are already hypoxemic and have airway closure at abnormally high lung volumes, they suffer deterioration of gas exchange when breathing at low lung volumes.

Progressive increases in pulmonary arterial pressure may occur in adults who have repeated bouts of arterial desaturation from the sleep apnea syndrome. Therefore, it may seem a foregone conclusion that supplemental oxygen should be used to prevent desaturation in those patients who show it. But the present study and the report by Stokes et al found the most severe degrees of desaturation in the patients with the most advanced lung disease. These patients are likely to have carbon dioxide retention and some will respond to supplemental oxygen by marked decreases in ventilation. Since oxygen therapy is particularly likely to become intermittent in the sleeping, unattended patient, it can cause previously unexperienced depths of oxygen desaturation whether any changes due to sleep itself occur or not. Even if the inspired concentration of oxygen is steady, a decrease in ventilatory drive may cause retention of secretions. It follows that patients with the most advanced lung disease present the greatest need both for supplemental oxygen and for a controlled setting to evaluate its effect. Sykes et al have contracted this first principle of controlled oxygen therapy into a formula[1]: "If intermittent oxygen therapy is safe, it is unnecessary. If oxygen is needed, it is dangerous."

Hemoglobin Desaturation

Its Occurrence During Sleep in Patients With Cystic Fibrosis

Paul W. J. Francis, MB, BS, FRACP; Nestor L. Muller, MD; Dennis Gurwitz, MB, BCh, FRCP(C); David W. A. Milligan, MB, BS, MRCP; Henry Levison, MD; A. Charles Bryan, MB, BS, PhD, FRCP(C)

• Sleep studies were performed in 20 clinically stable cystic fibrosis (CF) patients (mean age, 18.2 years) to determine the magnitude of fall in hemoglobin saturation (Sao_2) during sleep and to relate these changes to pulmonary function and echocardiographic findings. Five healthy young adults served as controls. In both groups, the maximum fall in Sao_2 was seen during rapid eye movement (REM) sleep. The mean maximum fall in the control group during REM sleep was 2.0% (range, 1% to 3%), compared with 7.4% (range, 1% to 23%) in the CF group. Of the 11 patients in whom right ventricular systolic time intervals were obtained, eight of the nine patients with falls in Sao_2 greater than 3% during REM sleep had echocardiographic evidence of pulmonary hypertension. Repeated episodes of desaturation during sleep may contribute to the development and progression of cor pulmonale in CF patients.

(*Am J Dis Child* 134:734-740, 1980)

Cor pulmonale is a common complication of cystic fibrosis (CF). Autopsy studies have reported an incidence of 70% to 80%.[1,2] Although the prognostic significance of mild pulmonary hypertension is not fully known, once overt right ventricular failure has developed the prognosis is extremely grave,[3,4] with a median survival in one series of only months.[5]

Hypoxia is thought to be the major etiological factor in the development of cor pulmonale in CF.[6,7] Studies in adults with chronic obstructive lung disease (COLD) have demonstrated repeated episodes of falls in hemoglobin saturation (Sao_2) during sleep[8-10] associated with transient pulmonary hypertension.[11,12] It has been suggested that in some patients these episodes may eventually lead to sustained pulmonary hypertension and cor pulmonale.[11-14]

Recently, it was shown that CF patients frequently have echocardiographic evidence of cor pulmonale that would not have been expected on the basis of their pulmonary function data or waking Pao_2.[15,16] Therefore, we investigated the incidence of hemoglobin desaturation during sleep in CF as a possible etiological factor in the development of cor pulmonale. As there are conflicting data on the magnitude of hemoglobin desaturation during sleep in apparently normal older adults,[9,12,17-20] a group of healthy young adults was also studied to serve as a control.

MATERIAL AND METHODS

The patient group consisted of 20 CF patients (nine female and 11 male) with a mean age of 18.2 years (range, 8.8 to 29.3 years). All were studied when their pulmonary status was stable as assessed by clinical, radiological, and pulmonary function criteria. The patients were selected solely by their willingness to participate in the study.

The control group consisted of five nonobese young adults (three women and two men) with a mean age of 26.7 years (range, 22.4 to 30.4 years). None had a history of lung disease, cigarette smoking, snoring, or sleep disturbance.

The sleep studies were commenced at the usual time of retiring (usually around midnight), and were continued until around 6 AM. The EEG was recorded as a bipolar single channel from surface electrodes placed in the left frontal and parietal regions. The electro-oculogram was recorded from a pair of electrodes placed at the outer canthus of each eye. Hemoglobin

saturation was monitored with an ear oximeter. Rib cage and abdominal movement were monitored by linearized magnetometers placed in the midline at the level of the nipple and at 1 cm above the umbilicus, respectively. In all subjects, the signals were recorded on an eight-channel recorder. The subjects were observed throughout the sleep study to note the presence of snoring, as well as positional or behavioral changes.

To examine the reproducibility of the sleep study findings, two CF patients had repeated studies performed several weeks after the initial study. For the second study, each subject had pulmonary function results similar to those measured at the time of the initial study.

Sleep state was assessed as wakefulness, rapid eye movement (REM) sleep, or non-REM sleep, according to standard criteria.[21] All Sao_2 values subsequently referred to are taken as the minimum values for each sleep state. Falls in Sao_2 values during sleep were calculated from the minimum waking Sao_2.

Pulmonary function studies were performed in CF and control subjects within 24 hours of the sleep study. Thoracic gas volume (TGV) and airways resistance (RAW) were measured in a constant volume body plethysmograph. In two patients in whom RAW and TGV were not measured, functional residual capacity (FRC) was estimated by the helium dilution technique. Inspiratory capacity and expiratory reserve volume were obtained from a 9-L water-filled spirometer, and values for total lung capacity (TLC), residual volume (RV), and RV/TLC were subsequently calculated. Forced vital capacity (FVC), forced expired volume in 1 s (FEV_1), and forced expiratory flow during the middle 50% of the FVC were measured with a Wedge spirometer. Results for TLC and flow rates were expressed as the percent of normal values for this laboratory.[22] Blood gas analysis was performed in CF patients using arterial (12 patients) or arterialized capillary samples (eight patients).[23] Shwachman-Kulczycki scores were determined in all patients.[24]

M-mode echocardiography was performed with the patients supine and their right shoulders slightly elevated (approximately 30°), using transducers selected for each patient with a commercially available ultrasonoscope connected to a strip chart recorder. Right ventricular anterior wall thickness (RVAW), right ventricular internal dimensions (RVD), and the right ventricular preejection period to ejection time (RV = PEP/ET) ratio were measured and compared with normal values.[25-27] The significance of differences between paired and nonpaired data was assessed with Student's t test.

RESULTS

Control Group

All control subjects had normal pulmonary function. The sleep data for the control group are given in Table 1. The mean minimum Sao_2 during REM sleep (95.4% ± 1.3%) was significantly lower than that for the awake state (97.4% ± 0.9%, $P < .005$). The mean minimum Sao_2 during non-REM sleep (96.8% ± 0.8%) was not significantly different from the minimum waking value. The maximum fall in Sao_2 was 1% in non-REM sleep and 3% in REM sleep. In none of these subjects was the desaturation associated with central apneic episodes (as defined by a cessation of respiratory movement for longer than 10 s), snoring, or paradoxical movement of the rib cage and abdomen.

CF Group

The majority of CF patients had moderate to severe lung disease. This is reflected in the pulmonary function data given in Table 2. It can be seen that there was no significant difference between the sexes with respect to any of the pulmonary functions measured.

The sleep data for the CF group are given in Table 3. There were no significant differences between the sexes with respect to any of the sleep variables documented. Both the largest fall in Sao_2 (23% in patient 9) and the lowest Sao_2 (48% in patient 6) were recorded during REM sleep. The percent of total sleep time monitored during which the patient's Sao_2 was more than 3% below the minimum awake value ranged from 0% to 43% (mean, 7.3% ± 1.8%).

For the CF group as a whole, the mean maximum fall in Sao_2 during REM sleep (7.4% ± 5.7%) was significantly greater than that seen during non-REM sleep (3.5% ± 2.0%, $P < .001$). The mean minimum Sao_2 during non-REM sleep (88.2% ± 7.2%) was significantly lower than that for the waking state (91.7% ± 5.8%, $P < .001$). The mean minimum REM Sao_2 (84.3% ± 11.0%) was significantly lower than both the mean minimum non-REM ($P < .001$) and awake Sao_2 values ($P < .001$). There were significant correlations between the maximum falls in Sao_2 during both REM and non-REM sleep and the severity of the lung disease (Table 4).

On comparing the CF and control groups (Table 5), it can be seen that the mean maximum falls in Sao_2 during both non-REM and REM sleep in the CF group were significantly greater than the corresponding falls in the control group. In addition, the mean minimum Sao_2 for the CF group when awake and during both non-REM and REM sleep were all significantly lower than the corresponding values in the control group.

A consistent feature of the desaturation during REM sleep was the lack of arousal as assessed by behavioral criteria after the maximum falls in Sao_2 (Fig 1). Of the total of 45 REM epochs monitored, in only five was there any suggestion of an arousal response associated with the maximum fall in Sao_2. In these latter five instances, it was not possible to determine if the movements observed represented true arousal responses or merely phasic muscular activity normally seen during REM sleep.

*REM indicates rapid eye movement; Sao_2, hemoglobin saturation; RVAW, right ventricular anterior thickness; RVD, right ventricular internal dimensions; and RV-PEP/ET, right ventricular preejection period/ejection time ratio.
†Number indicates the percent of total sleep time in which there was a greater than 3% fall in Sao_2.
‡The upper limit of the normal range for RVAW and RVD are shown in parentheses.
§The upper limit of the normal range for RV-PEP/ET ratio is 0.35.

In 18 patients in whom two or more epochs of REM were monitored, the maximum fall of Sao_2 in each epoch for a given individual was reproducible. In two subjects (patients 6 and 17), repeated sleep studies were performed six and four weeks, respectively, after the initial study. For both patients, the degree of airway obstruction and hyperinflation were similar on both occasions. The maximum falls in Sao_2 in both non-REM and REM sleep were reproducible in these two patients.

Large falls in Sao_2 during REM sleep as exhibited by two women, patient 6 (22%) and patient 9 (23%) (Table 3), seem to be associated with a poor prognosis, as both patients died of respiratory and right ventricular failure within three and five months, respectively, of the sleep study. Autopsy results confirmed the presence of right ventricular hypertrophy. Left ventricular wall thickness and RVAW in patient 6 was 0.9 cm and 1.2 cm (normal, 0.3 cm), respectively. The corresponding values in patient 9 were 1.7 cm and 0.7 cm (normal, 0.3 cm), respectively. A third woman, patient 8, who had a maximum fall in Sao_2 during REM sleep of 5% (Table 3), also died of cardiorespiratory failure within two months of the sleep study, but an autopsy was not performed.

The echocardiographic data are given in Table 3. Three out of 15 patients had increased RVAW; 11 had increased right ventricular cavity size; and the RV-PEP/ET ratio was increased in eight of the 11 patients in whom it could be assessed. Eight of nine patients with a maximum fall in Sao_2 of greater than 3% during REM sleep had abnormal RV-PEP/ET ratios (Fig 2).

For the CF group as a whole, there was no significant correlation between RVAW, the RV-PEP/ET ratio and pulmonary function parameters, and the minimum waking Sao_2. Similarly, there was no significant correlation between RVAW or the RV-PEP/ET ratio and the degree or duration of desaturation during sleep.

COMMENT

Control Group

The relatively small falls in Sao_2 during sleep in the present control group are consistent with earlier reports,[17-19] but are at variance with a study of apparently normal adults that reported falls in Sao_2 of up to 29% during sleep.[20] However, this latter study included older, obese men who snored heavily, and therefore may have included subjects with early forms of the sleep apnea syndrome.[28,29] None of the subjects in the present control group were obese or snored. Furthermore, none had central apneic episodes. This is consistent with previous reports, in which periodic breathing with apneic episodes

*REM indicates rapid eye movement; Sao_2, hemoglobin saturation.

UNIVERSITY OF MISSISSIPPI MEDICAL CENTER LIBRARY

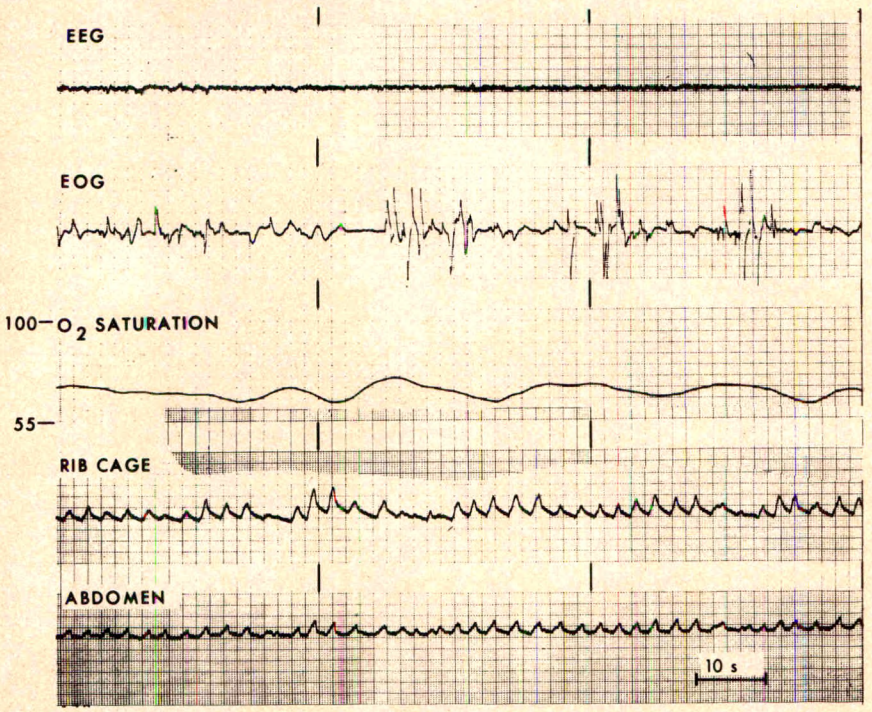

Fig 1.—Portion of rapid eye movement (REM) sleep in patient 9, whose minimum waking hemoglobin saturation (Sao_2) was 84%. After short episodes of hypoventilation associated with bursts of REM, there are falls in Sao_2, reaching values as low as 62% without any behavioral evidence of arousal response. As transition to REM sleep is not shown, fall in functional residual capacity is not apparent in this figure.

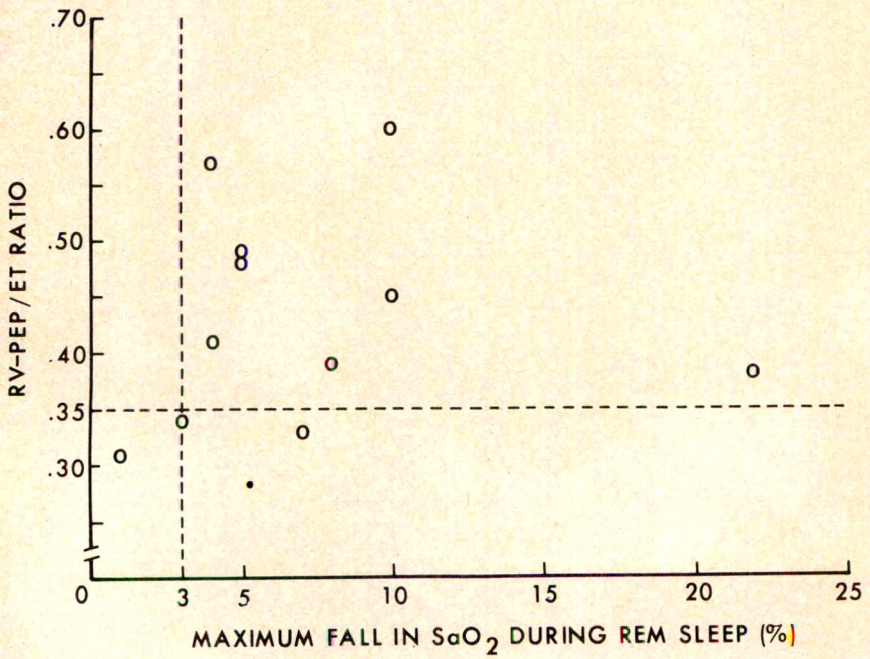
Fig 2.—Right ventricular preejection period/ejection time (RV-PEP/ET) ratio (normal, 0.35) plotted against maximum fall in hemoglobin saturation (Sao_2) during REM sleep. Upper limit of 3% fall in saturation is derived from control group.



during REM sleep was not seen in young adults,[30,31] but was frequently seen in healthy adults older than 40 years of age.[30,32]

The falls in Sao_2 values during REM sleep seems to be due to a decrease in tonic respiratory muscle activity resulting in a fall in FRC with consequent increased airway closure and increased intrapulmonary shunting.[33] This is consistent with the results of previous studies, which have demonstrated a loss of tonic activity in both the diaphragm[34] and intercostal muscles[35] during REM sleep in healthy adults. Superimposed on this were short episodes of hypoventilation, usually accompanying bursts of REM, that led to further falls in Sao_2.[33]

CF Group

In the CF group, the maximum falls in Sao_2 were seen during REM sleep. As in the control group, the desaturation was associated with short periods of hypoventilation (Fig 1) superimposed on a reduction in FRC. In none of these patients was the desaturation associated with apneic episodes or snoring. These findings are consistent with those reported in CF patients of similar mean age as the present study group.[36] However, these findings contrast with reports of adults with COLD, where the desaturation during REM sleep could not be explained by the pattern of breathing observed during this sleep stage.[37] In addition, studies in adults with COLD have described marked desaturation occurring in association with snoring,[9] as well as shorter episodes of desaturation due to hypoventilation and apnea that occurred mainly in non-REM sleep.[37] These mechanisms were not seen in the present study.

Thus, the hemoglobin desaturation during REM sleep in the CF patients seems to be due to mechanisms seen in healthy subjects of similar age. The larger falls in Sao_2 seen in the CF group compared with the control group partly reflect the fact that many of these patients had awake saturations near or on the steep portion of the oxyhemoglobin dissociation curve. Consequently, a given fall in Pao_2 would result in greater falls in Sao_2 in the CF patients as compared

with control subjects. In addition, because CF patients have an increased tendency for airway closure to develop,[38] the loss in FRC would result in a greater increase in intrapulmonary shunting as compared with control subjects.

Previous studies in the waking state have described only small shifts to the right in the oxyhemoglobin dissociation curve in CF.[39] As changes in $Paco_2$ and pH were not monitored during sleep in the present study, it is not possible to predict their effect on the position of the oxyhemoglobin dissociation curve. Nevertheless, it seems reasonable to assume that the low Sao_2 values recorded during REM sleep in many patients (Table 3) correspond to quite low Pao_2 values.

With only a single night's sleep being monitored, it is not possible to draw any firm conclusions as to the quality of sleep in these patients. However, it was apparent that some patients with severe lung disease had episodes of coughing in both non-REM and REM sleep that led to arousal and consequent sleep disturbance.

It is interesting to note that there was no significant difference between the sexes with respect to the degree of hemoglobin desaturation seen during both non-REM and REM sleep. This contrasts with the results of a recent study of apparently normal adults, in which hemoglobin desaturation was not seen in women but was frequently observed in men.[20] Furthermore, of the 54 adults with COLD in whom hemoglobin desaturation during sleep has been reported, 47 have been men.[8,9,12,37,40] This most likely reflects the higher incidence of COLD among men, as well as the tendency in men for snoring and hemoglobin desaturation during sleep to develop with increasing age.[20,29]

In the present study, the maximum falls in Sao_2 during REM and non-REM sleep correlated significantly with the severity of the lung disease (Table 4). This contrasts with one study of adults with COLD where changes in Pao_2 during sleep were not related to the degree of airways obstruction.[8] In another study of adults with COLD, the maximum falls in Sao_2 during sleep correlated with the FEV_1-vital capacity ratio, but not with other spirometric parameters, the waking Sao_2, or the waking Pao_2.[9] These differences may be due to the larger number of patients and the wider range of pulmonary function encompassed by the present study, as well as the different mechanisms that contributed to the desaturation seen in adults with COLD.[9,37]

The lack of behavioral changes consistent with an arousal response to desaturation during REM sleep is consistent with recent observations in dogs, in which a diminished arousal response to both hypoxia and hypercapnia has been demonstrated during REM sleep.[41,42] Although the diminished arousal response in the CF patients is likely to lead to less sleep disturbance, it may also mean that the patients experience more profound and more prolonged desaturation during REM sleep.

The relationship between these repeated episodes of desaturation during sleep and the echocardiographic findings is not fully known. However, there is evidence to suggest that intermittent hypoxia in experimental animals leads to sustained pulmonary hypertension and right ventricular hypertrophy. Unger and co-workers[43] have shown that acute intermittent hypoxia in dogs produces progressive increases in mean pulmonary artery pressure with successive hypoxic stimuli. These workers suggested that the intermittent nature of the hypoxic stimulus may have been important in the observed response, as continuous hypoxia was not associated with a progressive rise in mean pulmonary artery pressure. More prolonged studies in rats have shown that intermittent exposure to hypoxia alone[44] or to hypoxia and hypercapnia[45] leads to sustained pulmonary hypertension and right ventricular hypertrophy.

Recent studies in adults with the sleep apnea syndrome have demonstrated progressive increases in pulmonary artery pressure with repeated hypoxic episodes.[46] Similar studies in adults with COLD have demonstrated episodic pulmonary hypertension associated with recurrent desaturation during sleep.[11,12] It has been suggested that with time the episodic pulmonary hypertension in these patients may become sustained, leading to right ventricular hypertrophy and eventual right ventricular failure.[11-14]

In the present study, six patients had RV-PEP/ET ratios greater than 0.40 (Table 3), which has been shown to be indicative of severe pulmonary hypertension.[47] None of these patients had a waking Pao_2 of less than 50 mm Hg, which has been shown previously to indicate the presence of severe pulmonary hypertension.[3] Therefore, it is postulated that the repeated episodic desaturation seen in the CF group during sleep may be a significant etiological factor in the development and progression of cor pulmonale in these patients. It is possible that nocturnal oxygen therapy may be of value in such patients. Well-controlled trials that consider patient selection, inspired oxygen concentration, and duration of oxygen therapy will be necessary to fully define the place of such therapy in the routine management of CF.

This investigation was supported in part by travel grants from the Royal Australasian College of Physicians, the Australian College of Paediatrics, and the Asthma Foundation of Victoria.

60 YEARS AGO IN THE AJDC

A Study of Pneumonia in Infancy and Childhood During Recent Epidemics

The "most virulent epidemic that spread with terrifying rapidity over two hemispheres" in the 1918 and 1919 years affected children as well as adults. It was said that children were less severely affected but mortalities over 50 per cent. are recorded from the pneumonias that commonly followed. A total of 336 pneumonias observed in children under 6 years of age during these two years at the Mount Sinai Hospital were analyzed. Of these, 288 were considered bronchopneumonias, 48 lobar pneumonias. Bronchopneumonia occurred predominantly among those under 2 years, lobar pneumonia being seen more commonly over 2 years of age. Mortality was higher with the former, 18 per cent.; 10 per cent. among lobar pneumonias. These risk figures corresponded closely to those observed previously in nonepidemic years.

Bacterial agents cultured were usually the influenzae bacillus, pneumococcus, streptococcus, or staphylococcus. Two infants with low leukocyte counts of 4,000/u mm died and differential counts with below 50 per cent. polymorphonuclears had a bad prognosis. One child with a leukocyte count of 86,000 made a rapid recovery.

The most frequent complication was otitis media (seventy-five cases). Empyema developed in seventeen cases. "Meningism" and lethargic encephalitis were infrequently observed. There was one case of pneumococcal meningitis.

Most important in treatment was hygienic care and efficient nursing. Daily milk of magnesia and enemas were routine and 10 to 20 drops of whiskey every four hours produced temporary stimulation. Dry cupping was condemned. The fretful nervous mother was excluded, keeping the patient in a sunny room with fresh air and quiet surroundings.—Henry Heiman, MD, New York (20:119-123, August 1920).

Sleep Hypoxemia in Young Adults With Cystic Fibrosis

Dennis C. Stokes, MD; John T. McBride, MD; Michael A. Wall, MD; Giuseppe Erba, MD; Denise J. Strieder, MD

• **Hypoxemia, obstructive apnea, and disordered breathing during sleep have been documented in adult patients with chronic obstructive pulmonary disease. We studied sleep, oxygen saturation, and breathing in nine patients (ages 17 to 26 years) with cystic fibrosis (CF) lung disease by means of all-night polygraphic tracings. Two had brief episodes of oxygen desaturation during rapid eye movement (REM) sleep, and one patient with severe disease had prolonged desaturation with episodic worsening associated with disordered breathing in REM sleep and with cough. No patient had apnea or any evidence of upper airway obstruction, in contrast with studies of older patients. In three patients, nocturnal coughing contributed to disruption of sleep cycles. Sleep oxygen desaturation may contribute to the development or progression of cor pulmonale in some patients with CF, but it seems to be most severe only in those with advanced disease.**

(*Am J Dis Child* 134:741-743, 1980)

Most patients with cystic fibrosis (CF) suffer from obstructive lung disease at an early age. As the lung disease progresses, they frequently have early morning fatigue, headache, and poor sleep. Many CF patients also have worsening hypoxemia in the supine position,[1] blunted sensitivity to carbon dioxide,[2] and upper airway obstruction with chronic infection and nasal polyps,[3] all of which can affect breathing during sleep.

For editorial comment, see p 733.

In adult patients with chronic obstructive pulmonary disease (COPD), arterial oxygen desaturation is known to develop in association with prolonged apneas, upper airway obstruction, or disordered breathing during sleep.[4-10] Significant nocturnal falls in arterial saturation as described in these patients could be a significant stimulus for the development of pulmonary hypertension and cor pulmonale in CF patients.

To assess the importance of respiratory disorders during sleep in the natural history of CF, we monitored sleep stage, respiration, and oxygen saturation during all-night sleep in a group of CF patients.

SUBJECTS AND METHODS

We studied eight young adults and one child with CF lung disease of varying severity. Clinical status, summarized as a Shwachman score,[11] and results of pulmonary function tests are listed in the Table. The patients had been admitted to Children's Hospital Medical Center, Boston, because of exacerbation of pulmonary symptoms without pneumothorax or hemoptysis. They were studied near the end of their hospital stay, to allow full benefit from therapy and acclimatization to the hospital. During the study, they slept in their own hospital bed in the EEG sleep laboratory. All patients were receiving antimicrobial agents directed against *Pseudomonas aeruginosa*, and three (patients 1, 5 and 7) were receiving standard doses of theophylline. Informed consent was obtained before the study as approved by the Committee on Clinical Investigation of Children's Hospital Medical Center.

Sleep was monitored[12] with a six-channel EEG tracing, oculogram, and mentalis electromyogram. Movement, cough, and other artifacts were recorded by an observer on the EEG tracing. For each minute of sleep, the tracings were classified into wakefulness, stages 1, 2, 3, or 4 of sleep, or rapid eye movement (REM) sleep. Nasal and mouth airflow were monitored with thermistors taped at the mouth and nose, and a single-lead ECG with chest electrodes. Relative directions of rib cage and abdominal motion were recorded with magnetometers.[13] Oxygen saturation was monitored continuously with an ear oximeter and averaged over one- to five-minute intervals by inspection of the tracings. Nasal and mouth flow, rib cage and abdominal motion, and ECG were reviewed minute by minute for (1) heart rate, (2) respiratory rate, (3) apneic episodes longer than 10 s, and (4) upper airway obstruction, the latter indicated by absence of air flow despite continued chest and abdominal motion.

RESULTS

Sleep

The patients were able to complete one to four sleep cycles during total study, times ranging from 3.0 to 7.3 hours (mean, 5.6 hours). On the average, they spent 12% of study time in wakefulness, 15% in sleep stage 1, 29%

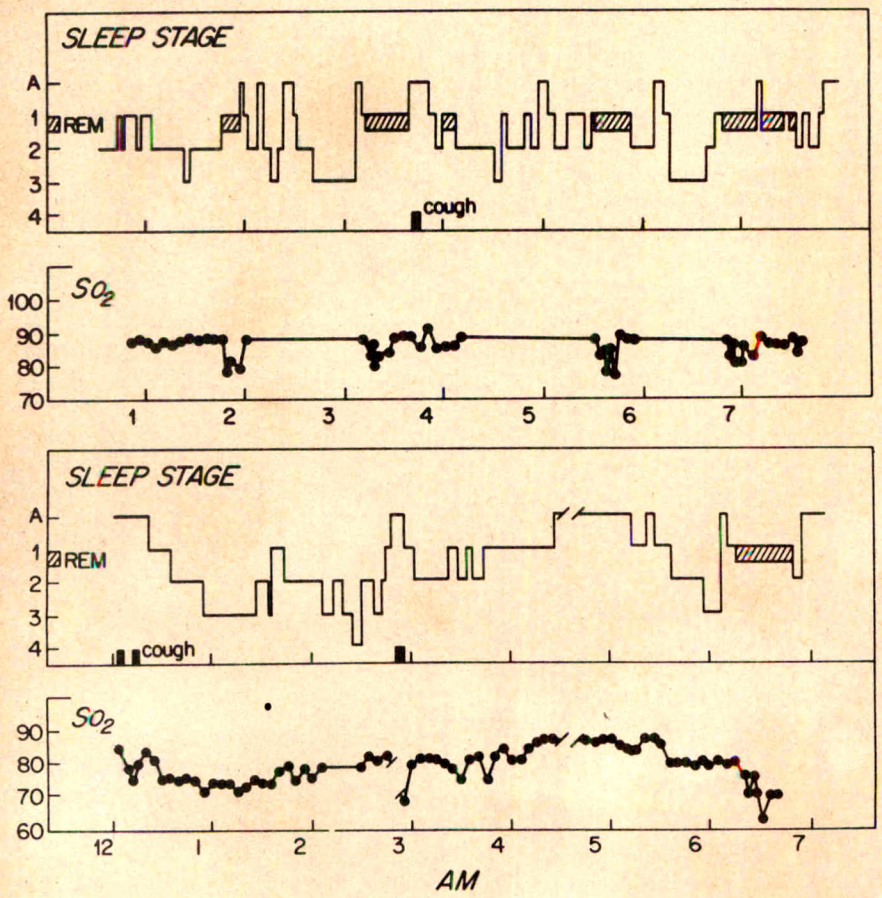
*FEV_1 indicates forced expiratory volume in 1 s; %P, percent of predicted value; RV/TLC, body plethysmographic values of residual volume to total lung capacity ratio.

†Fall in saturation associated with bout of coughing.

Sleep stage (A indicates awake), oxygen saturation (SO_2), and prolonged coughing episodes in two subjects during all-night sleep. Top, Patient 7; SO_2 falls with each period of rapid eye movement (REM) sleep and remains stable at other times (discrete points are then omitted). Sleep cycles are regular in spite of frequent arousals. Bottom, Patient 9; SO_2 remains low throughout all-night sleep, with precipitous fall during period of REM sleep. Oximeter was disconnected temporarily at 3 and 4 AM. Coughing episode at 3 AM is associated with arousal and failure to progress to REM sleep at end of sleep cycle.



in stage 2, 12% in stage 3, 14% in stage 4, and 18% in REM sleep.

Cough

In three patients, coughing was associated with sleep disorganization. Episodes of cough during stages 1 and 2 of sleep seemed to delay progression to deeper stages of sleep. In addition, protracted coughing during transition from deep sleep to lighter stages of sleep was occasionally followed by awakening rather than by a period of REM sleep, as would have been expected.

Oxygen Saturation

Five patients with moderate to severe disease (forced expiratory volume in 1 s of 31% to 63% predicted) had minimal changes in oxygen saturation regardless of sleep stage. One patient with mild disease (patient 1) showed a single fall in saturation of 10% after a severe coughing spell during light sleep. Two patients showed significant falls in oxygen saturation during REM sleep when, in the absence of body movements, the oximeter readings were most reliable. These falls lasted from five to 17 minutes (mean, ten minutes) and occurred during more than one sleep cycle (eg, Figure, top). Patient 9 had a low saturation in all sleep stages, with worsening desaturation after coughing spells and during REM sleep (Fig-

ure, bottom). For this patient, a second all-night study was performed, during which the same pattern was observed.

Apnea and Periodic Breathing

All patients had a few brief periods of apnea without change in oxygen saturation. No episode lasted more than 10 s and in no case was upper airway obstruction observed as abdomen and rib cage motion remained in phase. However, during REM sleep, whereas abdominal motion remained constant, the magnitude of rib cage motion tended to vary periodically in 40- to 50-s cycles. Although this observation indicated fluctuation of the tidal volume, actual values of tidal volume could not be derived from the data. Rib case periodicity showed no correlation with respiratory rate, which was irregular. This pattern of breathing during REM sleep occurred in most patients and was associated with a fall of oxygen saturation in two.

Arrhythmia

No bradycardia or arrhythmia occurred. Changes in heart rate with REM sleep were seen as expected.

COMMENT

We observed that in some patients with moderate to severe CF lung disease, sleep hypoxemia develops at night. Three subjects' changes in oxygen saturation were comparable in magnitude with those reported for adult patients with COPD, but they occurred in the absence of prolonged apnea or upper airway obstruction. During REM sleep, hypoxemia was associated with disordered rib cage motion, as demonstrated by the magnetometer tracings.

Variations in the rib cage contribution to breathing in normal persons during REM sleep has been documented by Tusiewicz et al.[14] They postulated that, in patients with COPD who have a flattened and inefficient diaphragm, reduced intercostal muscle tone in REM sleep could result in reduced ventilation. In our study, because we elected not to restrict patients' freedom of movement during sleep, the magnetometers could not be calibrated to give the exact contributions of rib cage and abdomen to tidal volume. However, we observed that the greatest falls in levels of saturation occurred in the two patients (7 and 9) who had the largest residual volume to total lung capacity ratios indicative of severe air trapping and flattening of the diaphragm, consistent with Tusiewicz's hypothesis.

The role of sleep hypoxemia in the development of cor pulmonale in CF remains uncertain. Five patients with moderately severe lung disease had trivial falls in levels of oxygen saturation. Of the four who had sleep hypoxemia, two had only brief episodes. Whether such brief episodes of desaturation can lead to sustained pulmonary arterial pressure changes will require direct pressure measurements during sleep.

Both obesity and increasing age are associated with increasing occurrence and duration of sleep apnea and hypoxemia in otherwise normal adults,[15] as well as in patients with COPD or the obstructive sleep apnea syndromes.[16] Patients with CF differ from patients with nonspecific COPD in that they are young and seldom obese. This seems to protect them from obstructive apnea described in older patients. None of our patients had evidence of upper airway obstruction and only one (patient 9) had profound and recurring falls in the levels of oxygen saturation during sleep. This patient had no evidence of right ventricular failure at the time of study, yet he died five months later of cardiorespiratory insufficiency. His case raises the possibility that sleep hypoxemia related to disordered breathing without apnea or upper airway obstruction may either contribute to the rapid deterioration occasionally seen in patients with advanced CF lung disease, or may be a sign of near-terminal illness.

In addition, we observed sleep disorganization associated with nighttime cough in three patients. Cough in another patient caused transient hypoxemia. Even though response to bronchial irritation[17] and mucociliary clearance[18] are depressed during sleep, the copious secretions characteristic of CF lung disease seem capable of triggering coughing spells and disrupting the expected progression of sleep stages.

Infectious Mononucleosis Complicated by Severe *Mycoplasma pneumoniae* Infection

James C. Dearth, MD, Kathleen H. Rhodes, MD

• A 14-year-old girl with infectious mononucleosis and secondary immunosuppression had severe dyspnea and cough, spiking fever, rales, and diffuse bilateral pulmonary infiltrates. The pulmonary disease progressed rapidly, necessitating empiric trials of antimicrobial agents. *Mycoplasma pneumoniae* was isolated from a lung biopsy specimen, transtracheal aspirate, and expectorated sputum, but the relatively long period required to isolate the organism delayed the microbiologic diagnosis. Serologic study of acute and convalescent serum samples confirmed the *M pneumoniae* infection. Clinical improvement was gradual, and the immunosuppression was transient. The patient's illness appeared to represent microbial synergism, with severe *M pneumoniae* infection complicating transient immunosuppression induced by infectious mononucleosis.

(*Am J Dis Child* 134:744-746, 1980)

Infectious mononucleosis is usually a self-limited lymphoproliferative disease resulting from infection with the Epstein-Barr virus. Transient suppression of immunity, especially cellular immunity, is well established during infectious mononucleosis.[1] However, reported clinical complications of this immunosuppression, especially secondary infection, are distinctly rare.[2,3]

Mycoplasma pneumoniae pneumonia is usually a self-limited respiratory infection.[4] Severe infections with *M pneumoniae* usually result from involvement of organs beyond the respiratory tract,[4] although severe respiratory tract involvement has been noted in patients with immunodeficiency syndromes.[5]

An association between infectious mononucleosis and *M pneumoniae* has been noted in a report involving two children who acquired *M pneumoniae* during convalescence from infectious mononucleosis,[2] though the immunologic status of these two patients was not reported. We describe here a patient who had infectious mononucleosis in whom suppression of cellular and humoral immunity was complicated by severe *M pneumoniae* pneumonia.

DIAGNOSTIC TECHNIQUES

Mycoplasma Isolation

Specimens included expectorated and transtracheal aspirate sputum samples, as well as tissue from lung biopsy. These were collected in sterile jars and transported to the laboratory as soon as possible. Specimens were spread over the surface of *Mycoplasma* agar plates with swabs. The swabs were then rotated and thoroughly extracted in diphasic broth. Procedures for incubation, examination of cultures, and the presumptive and confirmatory identification of *M pneumoniae* were then carried out according to published methods.[6]

Serologic Tests

The microtiter complement-fixation technique was used on serum specimens to measure antibody to *M pneumoniae*.[7] A patient's illness was considered to be associated with the potential pathogen when a fourfold change in serum titers occurred between acute and convalescent serum samples. A slide test for infectious mononucleosis heterophile antibodies was also performed.[8] The Epstein-Barr virus indirect fluorescent antibody test and the ox-cell hemolysin test were done at the Center for Disease Control, Atlanta.

REPORT OF A CASE

A 14-year-old girl was referred to the Mayo Clinic because of intermittent fever of 3½ weeks' duration. Initially, she had pharyngitis, otitis media, and cervical adenopathy. Results of a slide test for infectious mononucleosis heterophile antibodies were positive. She was given erythromycin for seven days. Ten days later, she returned with persistent fever. She was given daily injections of corticotropin for three days by a physician in her local community, presumably as treatment for fever; however, the fever recurred after four days. She was hospitalized four days for observation. An unproductive cough developed, and a roentgenogram of the chest two days before her referral showed a scant infiltrate in the left lower lobe.

Examination at our clinic disclosed a well-developed girl in no acute distress. She

Reprint requests to Section of Publications, Mayo Clinic, 200 First St SW, Rochester, MN 55901 (Dr Dearth).

coughed intermittently and was febrile (temperature, 39.4 °C). She had lost 6.8 kg during the 2½ weeks before examination. A roentgenogram of the chest disclosed an infiltrate in the left lower lobe that appeared to be unchanged from previously (Figure, left). At admission, hemoglobin level was 9.7 g/dL; platelet count, 141,000/cu mm; and leukocyte count, 3,300/cu mm, with 50% lymphocytes (many atypical) and 45% granulocytes.

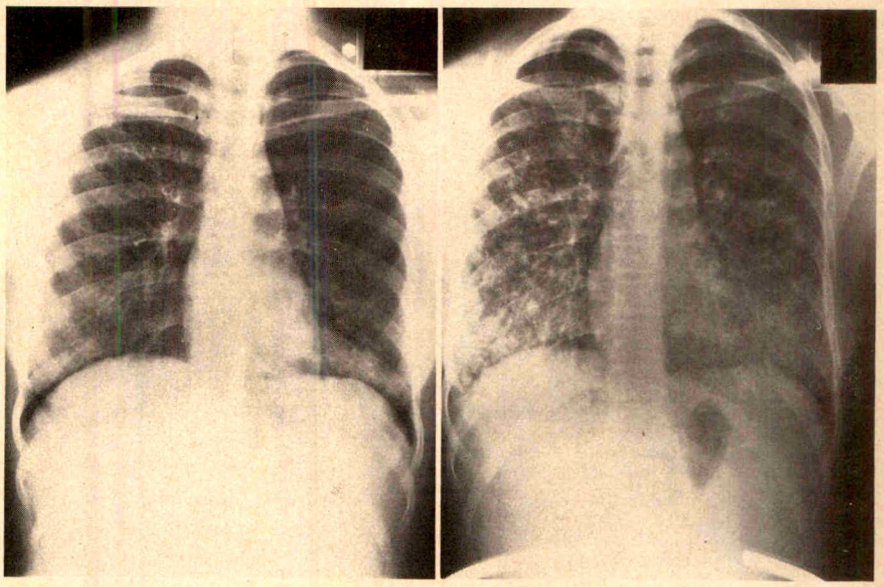
During the next three days, her cough increased in frequency and small amounts of clear, whitish sputum were produced. Cold agglutinin titer was less than 1:4; *M pneumoniae* complement-fixation titer was less than 1:2; and *Brucella* and fungal serology screen was negative. The leukocyte count was 3,900/cu mm, with 33% lymphocytes and 61% granulocytes. For the first time, rales were heard scattered in both lungs.

From day 4 through 7 after admission, her cough and sputum production increased. Fever spikes to between 40.0 and 40.6 °C began, and there was roentgenographic evidence that the infiltrates had increased dramatically (Figure, right).

Seven days after admission, a transtracheal aspirate was obtained. Gram's stain and bacterial cultures of the specimen were negative. The patient's respiratory rate was 40/min, and blood gas values on room air were as follows: Pa_{O_2}, 47 mm Hg; Pa_{CO_2}, 22 mm Hg; and pH, 7.51. She was given 40% oxygen by mask. The leukocyte count was 4,400/cu mm, with 14% lymphocytes and 83% granulocytes. IgA and IgM levels were within normal limits; however, the IgG level was 5.71 mg/mL (normal, 6.4 to 14.3 mg/mL).

Nine days after admission, the Pa_{O_2} stabilized at 60 mm Hg in 40% oxygen by mask. The leukocyte count was 3,300/cu mm, with 18% lymphocytes and 80% granulocytes. Therapy with cephalexin monohydrate, 1 g intravenously every four hours, was started. A bone marrow study showed left-shifted granulopoiesis with toxic granulation. Bone marrow cultures and stains were negative for bacteria and subsequently were negative for mycobacteria and fungi. Repeated fungal serologic studies and *M pneumoniae* titers were negative.

Eleven days after admission, the patient experienced continued deterioration, and an open lung biopsy specimen showed subacute inflammatory changes with some focal histiocytic proliferation. Silver, acid-fast, Gram's, and rhodamine stains were negative. Bacterial cultures were negative. Repeated cultures of urine, gastric aspirates, sputum, blood, and chest tube drainage were done for bacteria, fungi, mycobacteria, and *Brucella* organisms. All cultures were negative.



Chest roentgenograms. Left, At admission, infiltrate of left lower lobe. Right, Eight days later, diffuse bilateral infiltrates associated clinically with spiking fever and rales, increased sputum production, and cough with severe dyspnea.

Thirteen days after admission, with continued deterioration, the patient was given antituberculous therapy (isoniazid, rifampin, and gentamicin sulfate) after review of the lung biopsy specimen disclosed equivocal findings on the rhodamine stain. At this time, skin tests for *Candida albicans*, streptokinase, streptodornase, *Trichophyton*, and PPD were negative. The IgG level had decreased to 3.91 mg/mL, and the IgA and IgM levels remained within normal limits. The AM and PM plasma cortisone levels were above normal levels, with the expected diurnal variation.

Fourteen days after admission, the patient's condition began to improve gradually. On the 20th day after admission, she had normal T cells by E-rosette technique, but few normal B cells, as measured by surface immunoglobulin technique, were identified. Lymphocyte response to phytohemagglutinin was normal. Her condition continued to improve. On the 21st day, the transtracheal aspirate, sputum, and lung biopsy cultures were positive for *M pneumoniae*. She was given erythromycin, 500 mg every six hours, and was discharged five days later.

Serologic studies completed later on samples obtained at admission and seven and 21 days after admission confirmed the presence of antibody against Epstein-Barr virus at titers of 1:100 detected by the indirect fluorescent antibody test, along with decreasing levels (1:320 to 1:80) of ox-cell hemolysin titers. She was in good health two weeks after discharge. The IgG level had returned to normal (9.25 mg/mL). The *M pneumoniae* titer done by complement fixation was 1:32 at that time, as compared with less than 1:2 during hospitalization. She has remained in good health during the subsequent three years of follow-up.

COMMENT

The patient's illness appears to represent microbial synergism,[9] with transient immunosuppression induced by infectious mononucleosis predisposing to severe *M pneumoniae* pneumonia. Although the previous injections of corticotropin may have transiently interfered with her immunity, it is unlikely that any effect from the drug would persist with this severity for more than four weeks.[10] The patient had persistent lymphopenia and impaired cellular immunity, as evidenced by her negative skin test results for delayed hypersensitivity. She also had decreased B lymphocytes with hypogammaglobulinemia.

Many types of blood dyscrasias have been noted during infectious mononucleosis, including aplastic anemia,[11] agranulocytosis[12] and lymphopenia.[13] Hypogammaglobulinemia has been rarely found during infectious mononucleosis,[14] though the usual response is polyclonal hypergammaglobulinemia.[15] Occasional fatalities also have been reported in some families with a

genetic defect during infectious mononucleosis.[16]

Although transient immunosuppression during infectious mononucleosis is well established,[1] secondary infections are rare,[2,3] except in the presence of agranulocytosis.[12] One patient with infectious mononucleosis complicated by mixed bacterial infection has been described.[3] That patient had absent delayed hypersensitivity but normal serum immunoglobulin levels and granulocyte counts. An association between infectious mononucleosis and *M pneumoniae* also has been noted in two previously reported cases, but immunologic data were not included in that report and the *M pneumoniae* pneumonia apparently was not severe.[2] *Mycoplasma pneumoniae* pneumonia, usually a mild respiratory tract infection, is rarely fatal[4] and has been reported to be more severe in patients with immunodeficiency diseases.[5] Animal models of *M pneumoniae* infections suggest that both a cellular and a humoral immunity are involved in resistance to *M pneumoniae*.[17]

Our patient represents an uncommon complication of infectious mononucleosis from a relatively common respiratory pathogen. Two empiric trials of antibiotics failed to control the illness. The difficulty in culturing *M pneumoniae* and the prolonged period needed to obtain serologic confirmation of *M pneumoniae* infection delayed the diagnosis. This report serves to emphasize the potential for secondary infection during transient immunosuppression from infectious mononucleosis and the need to consider common but difficult to diagnose pathogens such as *M pneumoniae* in similar situations.

CORRECTION

Material Deleted.—In the Marginal Comment entitled "Regression and Clinical Research," published in the June issue of the JOURNAL (134:549-552, 1980), material was left out of the first sentence of the last paragraph, page 551; it should have read as follows: "One challenge to researchers is to distinguish whether a sample is indeed from an extreme tail of a distribution."

Persistently Negative Tuberculin Reactions

Their Presence Among Children With Culture Positive for *Mycobacterium tuberculosis* (Tuberculin-Negative Tuberculosis)

Phillip Steiner, MD; Madu Rao, MD; Minerva S. Victoria, MD; Hadi Jabbar, MD; Morris Steiner, MD

• Mantoux tests were performed on 200 children with culture-proven *Mycobacterium tuberculosis* infections. A group of 28 patients initially had negative reactions to 5 TU PPD-S. Of these, 17 had had extensive or overwhelming tuberculous disease at the time of admission, seven of whom reacted to 250 TU PPD; after a course of chemotherapy, all the survivors had positive reactions to 5 TU PPD-S. The 11 with less severe disease had negative reactions to 5 TU PPD-S and 250 TU PPD, as well as to PPD-A/B/G; in only two could a ready explanation be found for the negative reactor state. In general, a small number of children without life-threatening forms of tuberculosis may have persistently negative tuberculin reactions without any apparent cause. In such cases, other criteria for diagnosis must be relied on, such as lymphocyte transformation, culture, and biopsy.

(*Am J Dis Child* 134:747-750, 1980)

The tuberculin test remains the single most valuable test in the detection of tuberculosis both diagnostically and epidemiologically. Standard pediatrics textbooks list the efficacy of 5 TU PPD as 99% in the detection of active tuberculosis in children.[1,2] Recent studies in adults have indicated that this test is not as sensitive an index of infection as previously thought.[3-6] In a recent report by Rooney and co-workers, 21 of 100 adults with culture-proven tuberculosis had negative reactions to 5 TU PPD-T on admission to the hospital.[6] Most of these patients were seriously ill, and had protein depletion. Two weeks after initiation of antituberculous therapy and proper nutrition, only 5% had negative reactions. Of these, one had Hodgkin's disease, one leukemia, and one 80-year-old patient died four weeks after a second negative Mantoux test result. Only three did not suffer from any maladies that are known to alter delayed hypersensitivity, and these patients all recovered.

Tuberculin reactions can be depressed or absent in children who are critically ill with extensive disease; in those receiving corticosteroids or immunosuppressive therapy; after the administration of some live-virus vaccines; after certain viral diseases, such as measles; in patients with diseases that interfere with immunity; and during the incubation period of primary tuberculous infection. In addition, errors in technique of administration, the use of an inactive tuberculin solution, and errors in the interpretation of the test may also result in a false-negative tuberculin test result.[7]

To our knowledge, no studies are available of tuberculin skin reactivity in culture-proven tuberculosis in children in whom none of these factors were present. We performed a study of the number of patients with initially negative tuberculin reactions among 200 children with culture-proven tuberculosis, their clinical characteristics, and the number who had

Table 1.—Clinical Characteristics of Patients With Persistently Negative Reactions to 5 TU PPD-S

Case	Age, yr/mo	Sex	Clinical Features	No. of Skin Tests PPD-S 5 TU*	Period of Observation	Diagnosis
1	2/10	M	Fever, pleural effusion, hilar adenopathy; contact with tuberculosis; culture of pleural fluid grew *Mycobacterium tuberculosis*	8	10 mo	Hilar adenopathy, pleural effusion
2	1/0	M	Fever, pleural effusion, right upper lobe infiltrate; contact with tuberculosis; culture of pleural fluid grew *M tuberculosis*	4	4 mo	Primary pulmonary tuberculosis, pleural effusion
3	2/6	M	Fever, vomiting, cough, pleural effusion, left lower lobe infiltrate; contact with tuberculosis; culture of pleural fluid grew *M tuberculosis*	6	3 yr	Primary pulmonary tuberculosis, pleural effusion
4	3/0	M	Fever, cough, right lower lobe infiltrate; contact with tuberculosis; culture of gastric washings grew *M tuberculosis*	8	4 yr	Primary pulmonary tuberculosis
5	4/0	M	Fever, vomiting, cough, right middle lobe infiltrate; contact with tuberculosis; culture of gastric washings grew *M tuberculosis*	4	3 mo	Primary pulmonary tuberculosis
6	1/0	M	Fever, persistent right lower lobe infiltrate, no history of contact; culture of gastric washings grew *M tuberculosis*	5	3 mo	Primary pulmonary tuberculosis
7	0/3	F	Fever, cough, right middle lobe infiltrate; contact with tuberculosis; culture of gastric washings grew *M tuberculosis*	7	10 mo	Primary pulmonary tuberculosis
8	2/10	M	Fever, persistent right middle lobe infiltrate; no contact with tuberculosis; culture of gastric washings grew *M tuberculosis*	6	6 mo	Primary pulmonary tuberculosis
9	6/12	M	Heavy exposure to father who had extensive cavitary tuberculosis; culture of gastric washings grew *M tuberculosis*	8	4 yr	No demonstrable disease
10	9/0	M	History of exposure to tuberculosis, mass in superior mediastinum; culture of gastric washings grew *M tuberculosis*	6	2 yr	Leukemia
11	9/0	M	Extensive bilateral pulmonary infiltrates, fever, hepatomegaly, hilar adenopathy; culture of gastric washings grew *M tuberculosis* twice; Kveim test biopsy specimen showed noncaseating granuloma	10	2 yr	Sarcoidosis

*All patients reacted negatively to 250 TU PPD and PPD-A/B/G.

persistently negative reactions after recovery.

SUBJECTS AND METHODS

The patient group comprised 200 children, ranging in age from 1 month to 14 years, from whom strains of *Mycobacterium tuberculosis* were isolated on culture. They received treatment at the State University Hospital-Downstate Medical Center and Kings County Hospital Center, New York, during the years 1965 through 1974.

Tuberculin Tests

All children were tested with 5 TU PPD-S. Repeat tests were performed on those with negative reactions with 5 TU PPD-S, 250 TU PPD, and the nontuberculous mycobacterial antigens PPD-A/B/G. All tuberculin except the 250 TU were originally obtained from Lydia B. Edwards, MD, of the US Public Health Service (USPHS), and later from the Communicable Disease Center, Atlanta. The tuberculin material obtained from the USPHS was prepared in dilutions of 0.0001 mg/0.1 mL by the addition of buffered diluent to lyophylized PPD, and were said to retain their potency for nine months after the initial dilution.[8] The potency of the 5 TU PPD-S solutions used was confirmed by the fact that strongly positive reactions were obtained from other children tested with the same material at the same time the patients with tuberculin-negative reactions were tested.

After 1969, PPD solutions stabilized with sorbitan polyoxyalkalene derivative (Tween) were used, except for the 250 TU PPD, which was commercially obtained and freshly diluted for each test. The tests were performed intradermally in the forearm of the patient by the pediatric chest fellows and read by them at 48 hours. An area of 10 mm or more of induration was considered to be a positive reaction. Areas of 5 to 9 mm were classified as weak or doubtful reactions and 0 to 4 mm were considered to be negative reactions. Repeated tests on the patients with negative reactions were done with 5 TU PPD-S at intervals of one month until the time of discharge. Tests were repeated in some patients after discharge from the hospital in the pediatric chest clinic for as long as four years after performance of the initial tests. All children were given treatment with standard chemotherapy. Treatment was begun immediately, or soon after admission, on all patients with a positive tuberculin test and on those who had life-threatening disease, even if they had negative reactions. Treatment was delayed for seven of the nine patients with persistently negative reactions who had primary pulmonary infection, until the presence of tuberculosis was confirmed by culture (four to six weeks). The other two patients (Table 1, cases 9 and 10) were given treatment shortly after admission.

Laboratory Methods

The techniques for the isolation, identification, and susceptibility testing of *M tuberculosis* have been previously described.[9]

Table 2.—Results of Skin Testing on Admission and Discharge Among 200 Children With Positive Cultures For *Mycobacterium Tuberculosis*

Skin Reactivity Induration, mm	No. of Patients Tested (%)			
	Initial Tests		Final Tests	
	5 TU PPD-S	250 TU PPD-S*	5 TU PPD-S	250 PPD-S*

17*	3/0	F	+	0	0	0	Meningitis: died of disseminated intravascular coagulopathy 3 wk after admission

*Died; not retested.

RESULTS

There were 200 children, 108 boys and 92 girls, from whom *M tuberculosis* was isolated from sputum, gastric washings, spinal fluid, pleural fluid, or lymph nodes. Of these, 141 had primary pulmonary tuberculosis, of whom two had associated serious diseases, one with leukemia and the other with sarcoidosis. The remaining 59 patients had serious or life-threatening forms of tuberculosis, ie, meningitis, miliary tuberculosis, or bone tuberculosis, and two had congenital tuberculosis. All patients in the study were similar with regard to age, race, history of exposure to tuberculosis, and socioeconomic status.

On admission to the hospital, 163 (81.5%) had strong, positive reactions to 5 TU PPD-S, nine (4.5%) had weak or doubtful reactions (5 to 9 mm), and 28 (14%) had negative reactions. Seven of the 28 with negative reactions reacted to 250 TU PPD, but not to 5 TU PPD-A/B/G. On retesting with 5 TU PPD-S from one to six months after initiation of therapy, 182 (92%) had strong reactions and five (2.5%) weak reactions. Eleven (5.5%) had persistently negative reactions to 5 TU PPD-S, 250 TU PPD, and PPD-A/B/G (Table 2).

The characteristics of the patients with persistently negative reactions are given in Table 1. In Table 3 are given the characteristics of those patients who initially had negative reactions, but who then had positive reactions to 5 TU PPD-S after initiation of therapy.

COMMENT

A surprisingly large percent of the children (5.5%) with culture-proven tuberculosis had persistently negative tuberculin reactions. All but two of these children (Table 1, cases 10 and 11) did not have overwhelming disease, were well nourished, and had no apparent clinical evidence of an imunological deficiency. There were no demonstrable clinical differences between those with positive or negative reactions with primary tuberculosis with respect to age, onset of illness, symptoms, or socioeconomic status. There was a difference in the onset of treatment between these two groups, in that treatment was delayed in all but two patients in the group with persistently negative reactions until the diagnosis was established by culture (four to six weeks). Thus, early initiation of treatment was not a factor in the group with persistently negative reactions. Houk et al reported that those with positive reactions, if treated soon after exposure to tuberculosis, will revert to a tuberculin-negative state.[10] However, none of the patients in his report had demonstrable disease, as did eight of the nine of our patients who had persistently negative tuberculin reactions (Table 1, cases 1 through 9). The two other patients in this group, cases 10 and 11, had adequate explanation for their tuberculin-negative states; one

had leukemia and the other sarcoidosis. Excluding these two cases, the persistently negative reaction rate for all 200 culture-proven cases of tuberculosis was 4.5%. The persistently negative reaction rate for the 139 positive-culture patients with primary tuberculosis and no complicating disease was 6.5%. An additional 303 patients, not included in this study, received treatment at our institution for primary pulmonary tuberculosis during the study period. All had negative cultures and the diagnosis was based on a history and chest roentgenogram compatible with primary pulmonary tuberculosis, plus a positive Mantoux test.

It is of interest that all of the patients with initially negative reactions who reverted to a positive reaction state came from the group of patients who had serious or life-threatening forms of tuberculosis, whereas all those with persistantly negative reactions had primary pulmonary tuberculosis. From our data, no explanation can be given for this finding. One can speculate that since the more serious forms of diseaes occur after a primary infection, the disease process has been present for a longer time and that those patients were more heavily infected. Both of these factors might provide a greater antigenic stimulus to the host, which becomes manifested by positive skin reactivity during or after recovery. It is also possible that these patients had initially positive reactions who reverted to a negative reaction state with the onset of serious or overwhelming disease and again had positive reactions on recovery. In contrast, those with persistently negative reactions never manifested positive skin reactivity either before or after treatment.

These findings indicate that the Mantoux test cannot be relied on as the sole criterion for the diagnosis of tuberculosis, as a small but significant number of children with culture-proven tuberculosis (4.5%) who do not have severe or overwhelming disease and whose immune system is not apparently compromised will consistently fail to react to tuberculin. In such instances, other diagnostic procedures, such as lymphocyte transformation,[11] culture, and biopsy, may have to be used to establish the diagnosis.

It is highly improbable that our results are due to improper techniques or faulty test materials, as all tests were performed and read by trained fellows in pediatric chest disease.

Through 1969, diluted, nonstabilized tuberculin was used. This material has been reported to be unstable and in some instances to have been responsible for false-negative tuberculin tests.[12] The question of potency and stability of the tuberculin solutions used was raised when our first culture-positive, tuberculin-negative patient was encountered in 1965 (Table 1, case 7). Potency of the PPD-S was checked by testing several known positive reactors, and was found to give strong positive reactions. The potency of all the PPD-S solutions used to test the other culture-positive, tuberculin-negative patients was similarly assured by testing known positive reactors. Secondly, all patients with persistently negative tuberculin reactions had four or more tests, and a different vial of PPD-S was used for each test. These multiple tests with different vials of PPD-S virtually eliminated the possibility of faulty technique.

It is of interest to note the significant predominance of boys among the persistently negative reactor group (Table 1). Only one of 11 patients was a girl. The reason for the predominance of boys in this group is not apparent.

Ankyloblepharon Filiforme Adnatum

Congenital Eyelid-Band Syndromes

Yaacov Rosenman, MD; Susy Ronen, MD; Arthur I. Eidelman, MD; Michael S. Schimmel, MD

• Three infants had congenital eyelid bands, ankyloblepharon filiforme adnatum (AFA), in association with cleft lip and palate. A review of the literature of all previously reported cases of AFA was performed and a new classification of the various clinical types of AFA is proposed. This new classification should aid in genetic counseling.

(*Am J Dis Child* 134:751-753, 1980)

Ankyloblepharon filiforme adnatum (AFA) is a rare congenital anomaly that was first described by von Hasner in 1881.[1] The term describes the pathology of fine strands of tissue joining the upper and lower eyelids. The abnormality has been reported as an isolated finding, in association with other anomalies and as part of defined syndromes. We wish to report three additional cases of AFA that should further assist physicians in defining the teratogenetic implications of this entity. In addition, an attempt will be made to categorize the various conditions wherein AFA occurs so as to provide a rational guide for genetic counseling.

REPORT OF CASES

Case 1.—A 3,650-g first born male infant was born after an uncomplicated full-term pregnancy to unrelated healthy Sephardic Jewish parents. The maternal grandfather had a cleft lip. Physical examination showed complete right cleft lip and palate (Fig 1) and bilateral AFA (Fig 2). No other physical abnormalities were noted. Analysis of the chromosomes of the father and the infant showed a similar karyotype of 46 chromosomes with balanced reciprocal translocation—46, XY, t (4:16). The mother had a normal female karyotype. At the age of 3 days, the AFA was severed and one month later the cleft lip was repaired. Follow-up examination of the infant at age 6 months showed a normally grown infant with appropriate development.

Case 2.—A 3,300-g female infant was born after an uncomplicated pregnancy to unrelated Ashkenazic Jewish parents. The parents' phenotype was normal, except for a short upper lip in the father. The infant had a total bilateral cleft lip and palate and bilateral AFA. The AFA was released at age 3 months.

Case 3.—Four years later, a male sibling was born after an uncomplicated full-term pregnancy to the parents of case 2. The infant had a bilateral cleft lip and palate, bilateral AFA (Fig 3 and 4), and clinodactyly of both fifth fingers. The karyotype was normal. The AFA was released at age 3 months. Follow-up examination of the child at age 6 years showed no abnormalities.

A third pregnancy ended in an induced abortion during the first trimester. No pathological examination of the fetus was performed.

COMMENT

Normal fusion of the eyelids is purely epithelial, begins during the ninth week of gestation, and is complete by the 11th week.[2-3] In our cases, however, as in others,[1-3] the filiforme bands consisted of a core of vascularized connective tissue covered by epithelium. Thus, it is clear that the bands reflect a defect in the fusion process and not in the separation that occurs between the fifth and seventh months of gestation. Although the teratogenetic cause of this defect is not clear, it is not surprising that anomalies of the lips and palate occur with great frequency in association with AFA, as these structures begin their develop-

ment in the seventh week of fetal life and are complete by the ninth week of gestation. The AFA themselves are of minor clinical importance because they pose little functional or therapeutic problems. No increased incidence of refractive errors, strabismus, or amblyopia has been reported. The bands frequently resolve spontaneously after a few months[4] or may be released by a simple operative procedure. The major practical importance of this anomaly is that when it occurs, it should alert the physician to the presence of other anomalies and to the possibility that a particular genetic pattern may be present.

A review of the literature indicates that the infants with AFA can be classified into four separate patterns of presentation (Table 1). Type 1 includes cases in which no associated defect in either the proband or the family are noted. These occur sporadically in no particular genetic pattern.[5-7] Type 2 includes cases in which AFA is associated with severe life-threatening cardiac or CNS defects. These reports are of sporadic cases without any familial pattern.[8-10] Type

Table 2.—Type 4 Ankyloblepharon Filiforme Adnatum: Cleft Lip and Palate Associated*

Source, yr	No. of Cases	Anomalies	Family and Genetics
Lohlein,[14] 1930	1	AFA, cleft lip	Unknown
Test and Falls,[15] 1947; Van der Woode,[16] 1954	1	AFA, fistula labii inferioris	Eight with cleft lip and/or palate in 5 generations, autosomal-dominant, variable expressivity
Khanna,[17] 1957	1	AFA, cleft lip and palate	Sister with AFA
Lemtis and Neubauer,[18] 1959	1	AFA	Paternal uncle and 2 of his 3 sons, cleft lip and palate; probably recessive
Long and Blandord,[19] 1962	1	AFA, bilateral complete cleft lip and palate	Paternal aunt with cleft lip and palate
Gupta and Saxena,[20] 1962	2	AFA, cleft lip	Siblings
Pahwa and Sud,[21] 1966	1	AFA, cleft lip and palate	Unknown
Sood et al,[22] 1968	1	AFA, complete cleft lip and palate	Maternal aunt with cleft lip and palate
Ehlers and Jensen,[23] 1970	1	AFA, complete cleft lip and palate	Father and maternal aunt with cleft lip and palate; grandfather with cleft lip
Present study 1979	1	AFA, cleft lip and palate	Maternal grandfather with cleft lip; proband and father balanced chromosomal translocation
	2	AFA, bilateral complete cleft lip and palate	Siblings with normal karyotype; father with short upper lip; autosomal-dominant variable expressivity

*AFA indicates ankyloblepharon filiforme adnatum.

3 AFA occurs in association with ectodermal syndromes, such as the popliteal pterygium syndrome[11-12] and the ankyloblepharon ectodermal defect and clefting syndrome.[13] These patients have an autosomal-dominant pattern with variable degrees of expressivity.

Of greatest interest to the pediatrician is type 4 (Table 2) AFA.[14-23] In this type, cleft lip and palate defects have been noted either in the proband or in the extended family. Our three cases, no doubt, fit into this group and illustrate the problem of simple genetic definition. The majority of such infants described in the literature occur in families with definite propensity to cleft lip and palate. In some families, an autosomal-dominant gene seems to be present, whereas in others either an autosomal-recessive pattern predominates or a multifactorial cause is likely. What is relevant to the pediatrician, however, is the fact that the presence of a cleft lip or palate in one member of the family and AFA in another should alert one to the increased possibility of additional cases of cleft lip and palate appearing in subsequent children.

Chromosomal studies have not been previously reported with AFA. In the first case, a balanced translocation (46, XY, t [4:16]) was found in the proband and the father. Since the mother had a normal karyotype and familial cleft lip occurred in the maternal grandfather, no association of AFA with this translocation anomaly is likely. This is further supported by the normal karyotype pattern in the third case.

Our attempt to categorize the AFA syndrome into four types is no doubt open to debate. However, until further cases are reported and more detailed family studies are performed, a clearer definition of the genetics is unlikely. Until such time, the appearance of AFA in an infant should alert the clinician to the potential birth in the same family of other infants with associated anomalies and our guide should assist him in the counseling of such families.

Professor J. Chemke referred family 2 for study, and Ada Roseman, MD, performed the cytogenetic studies.

Group B Streptococcal Disease

Its Diagnosis With the Use of Antigen Detection, Gram's Stain, and the Presence of Apnea, Hypotension

David L. Ingram, MD; Elizabeth L. Pendergrass; Patricia I. Bromberger, MD; James D. Thullen, DO; Charles D. Yoder, MD; Albert M. Collier, MD

• Antigen detection was found to be a rapid and useful technique in diagnosing group B streptococcal (GBS) infections. Of the two techniques described, latex agglutination was more sensitive than countercurrent immunoelectrophoresis. Concentrated urine was the best body fluid to test with 100% containing antigen. Though no false-positive reactions were noted, this is a potential problem. Gram-positive cocci in the gastric aspirate were associated with severe systemic infections with these organisms in almost half of the neonates with clinical signs of infection or respiratory distress syndrome (RDS). There was only a 4% infection rate in clinically similar neonates without Gram-positive cocci in the gastric aspirates. Apnea and/or hypotension was seen commonly in both early onset GBS pneumonia and RDS, making this finding alone of little clinical use.

(*Am J Dis Child* 134:754-758, 1980)

Clinically, it is difficult to distinguish between early onset (≤ 7 days of life) group B streptococcal (GBS) pneumonia and respiratory distress syndrome (RDS).[1-2] Similarly, it is difficult to distinguish between GBS infections and infections caused by other organisms. A number of clinical and laboratory characteristics have been suggested as being useful in these situations. In studies with a small number of cases, the three characteristics reported to be more suggestive of early onset GBS pneumonia than RDS were the presence of GBS antigen in body fluids,[3-7] Gram-positive cocci in the gastric aspirate,[3,8] and the presence of apnea and/or shock in the first 24 hours of life.[8,9] The purpose of this study is to test the usefulness of these findings in identifying neonates with early onset GBS pneumonia vs RDS, and also to describe a latex agglutination (LA) test and countercurrent immunoelectrophoresis (CIE) test that may be used to detect GBS antigen in body fluids in early onset and late onset GBS disease.

From the Department of Pediatrics, (Drs Ingram, Thullen, Yoder, and Collier and Ms Pendergrass) University of North Carolina School of Medicine, Chapel Hill, NC, and the Maine Medical Center (Dr Bromberger), Portland, Me.

METHODS

Three studies were performed to evaluate the usefulness of antigen detection (study 1), Gram-positive cocci in the gastric aspirate (study 2), and the presence of apnea and/or hypotension (study 3 [Fig 1 to 3]) as indicators of GBS infections. The studies were performed simultaneously.

Patient Population

The study populations were the neonates hospitalized at the Wake County Medical Center, Raleigh, NC, and the North Carolina Memorial Hospital, Chapel Hill, between January 1976 and December 1978. During this time, 19 neonates had early onset GBS pneumonia. Of these, 16 had available body fluids tested for GBS antigen (study 1), 13 had gastric aspirate Gram's stains and cultures (study 2), and all 19 were monitored for apneic spells and hypotension (study 3).

Eight neonates had other types of early onset GBS disease other than pneumonia. Seven had body fluids available for antigen

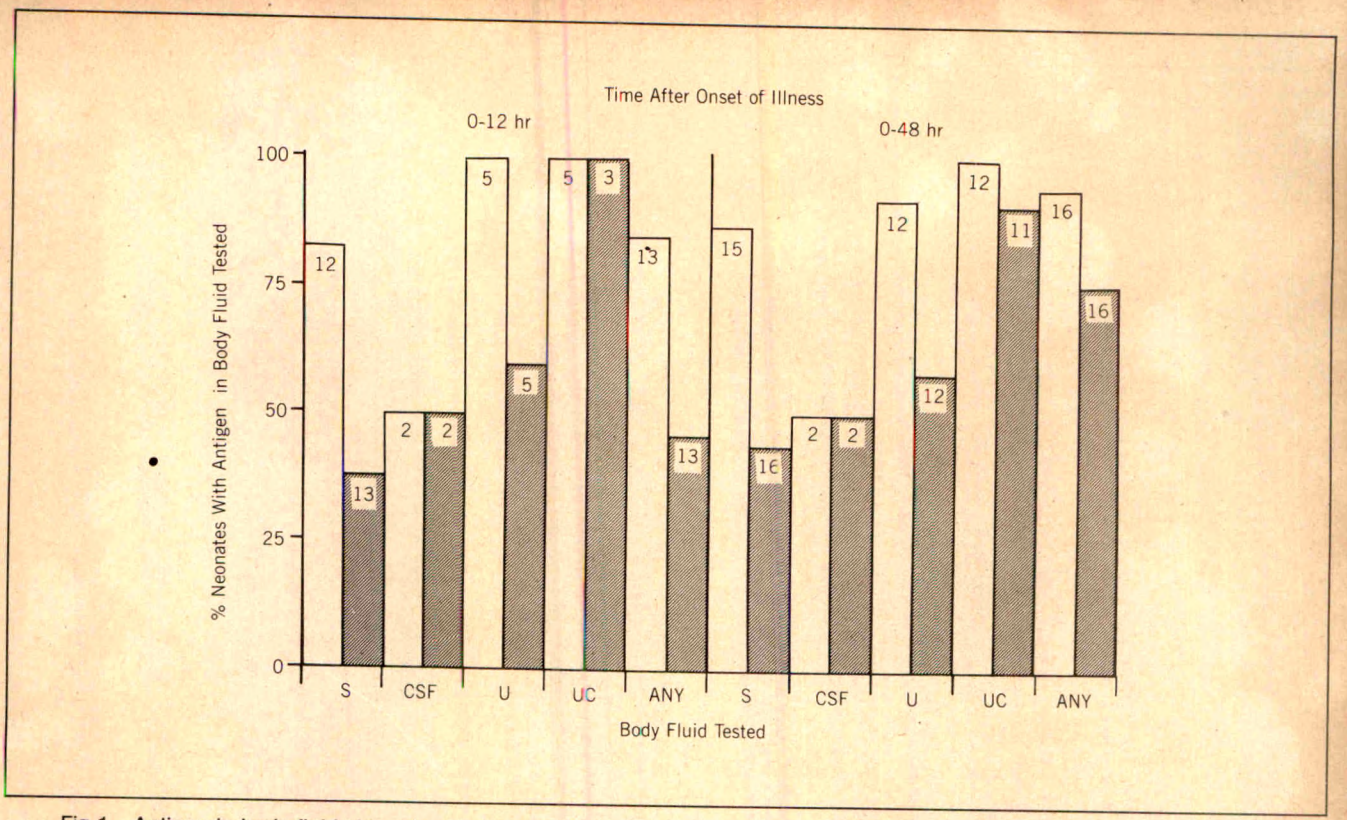

Fig 1.—Antigen in body fluids in early-onset group B streptococcal pneumonia (N = 16): shaded bar indicates positive by countercurrent immunoelectrophoresis; open bar, positive by latex agglutination; S, serum; U, urine; ANY, any fluid tested.

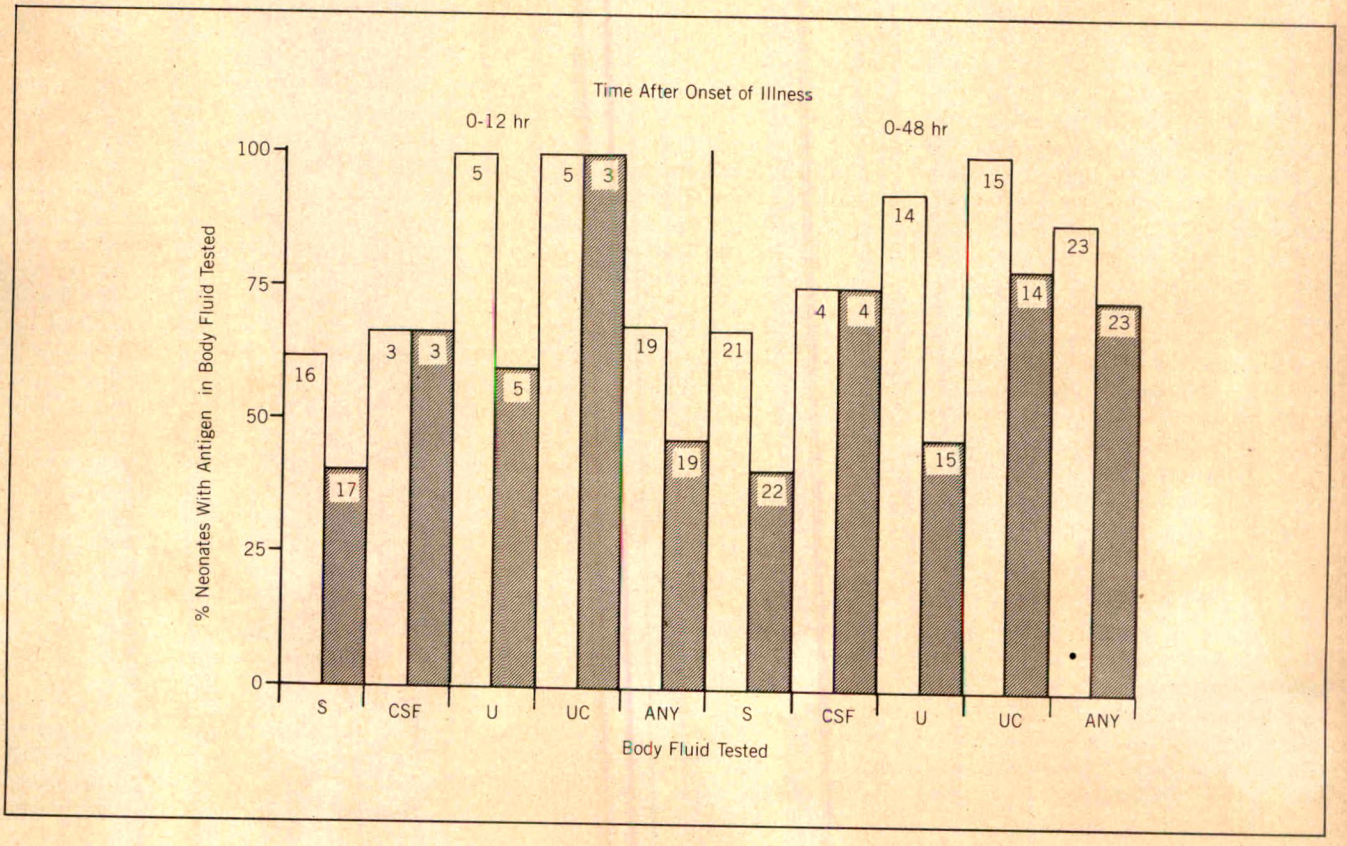
Fig 2.—Antigen in body fluids in all early-onset group B streptococcal disease (N = 23): shaded bar indicates positive by countercurrent immunoelectrophoresis; open bar, positive by latex agglutination; S, serum; U, urine; ANY, any fluid tested.



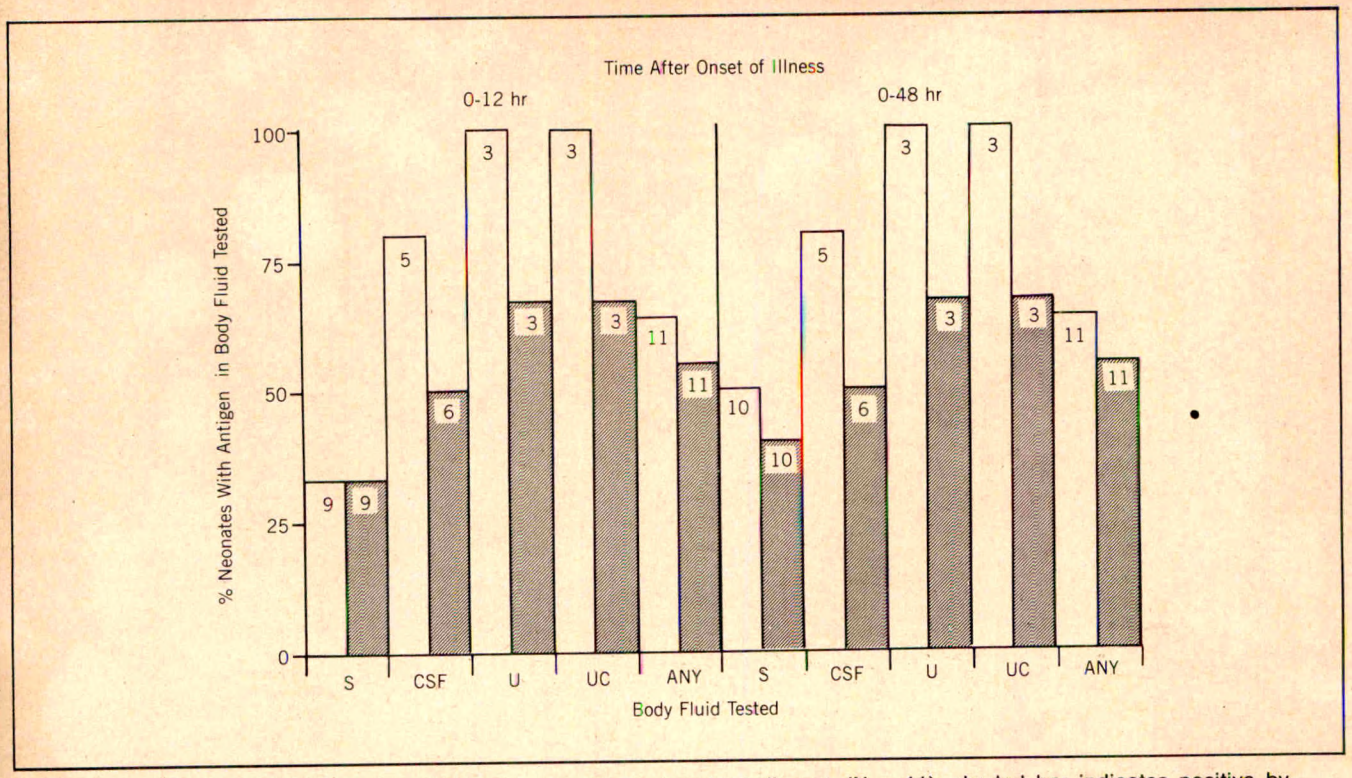


Fig 3.—Antigen in body fluids in late-onset group B streptococcal disease (N = 11): shaded bar indicates positive by countercurrent immunoelectrophoresis; open bar, positive by latex agglutination; S, serum; U, urine; ANY, any fluid tested.

testing (study 1). Three had gastric aspirate Gram's stains and cultures (study 2). Of 12 neonates with late-onset GBS disease, 11 had body fluids available for antigen testing (study 1).

One hundred and nine neonates who were clinically suspected of having an infection and/or RDS in the first 6 hours of life had a gastric aspirate Gram's stain and culture (study 2). These neonates were chosen by those pediatric house officers who routinely include these tests as part of their diagnostic studies in this situation. Other clinically similar neonates cared for by other house officers during the study period were not tested. Study 2 included 16 of 27 neonates with early onset GBS disease, the 11 others did not have gastric aspirate Gram's stains or cultures. Another population group was 100 consecutive neonates with RDS who were included in study 3.

Antigen Detection

All neonates in this study had a positive blood and/or CSF culture. Randomly collected samples of serum, urine, and/or CSF were obtained for testing by both LA and CIE. The time after the onset of clinical illness that they were obtained was noted. Available gastric aspirates that were positive on culture for GBS were tested by CIE. To check for the specificity of finding GBS antigen as an indicator of GBS infection, a negative control group of body fluids was obtained from the following: patients with *Haemophilus influenzae* type b, *Neisseria meningitidis* groups B, C, and Y; patients with *Escherichia coli* or *Streptococcus pneumoniae* meningitis and/or sepsis; neonates who were found not to be infected by culture; and neonates superficially colonized with GBS. Dilutions of 18-hour Trypticase soy broth cultures of GBS types 1a, 1b, 1c, 2, and 3 were used as positive controls. Body fluids, as well as urine concentrated in a disposable ultrafilter system (MINICON B-15) filter (Amicon Corporation, Lexington, Mass) were tested by LA and CIE.

The LA test used was developed by one of us (P.B.) and is a modification of the method of Severin.[10] The latex suspension was prepared by adding 1 part 0.81 μm of latex particles to either 1 part of the γ-globulin fraction of a 1:20 dilution of GBS grouping serum (Atlantic Antibody Co., Westbrook, Me) or whole serum antibody diluted 1:40 using GBS grouping serum (Burroughs Wellcome, Beckenham, England) in glycine-buffered saline (pH, 8.2). After two hours incubation at 37 °C, glycine-buffered saline plus 0.1% bovine serum albumin plus 0.15% sodium azide was added in a 1:1 ratio to the antiserum–latex suspension and stored at 4 °C. For testing, 20 μL of this dilute suspension was added to 40 μL of body fluid on a glass slide, mixed and agitated for three minutes. Agglutination showing at least definite clumps with only a slightly cloudy background was considered positive. Latex particles coated with normal rabbit sera served as a negative control.

Countercurrent immunoelectrophoresis was performed using a power pack (Hyland Austigen II, Hyland Labs, Costa Mesa, Calif) and plates refilled with 16 mL of 1% agarose (Fischer Scientific Co, Pittsburgh) in 0.05M sodium barbital-hydrochloride buffer (pH, 8.0). Three-millimeter wells spaced 5 mm apart were filled with 0.01 mL of body fluid or either GBS grouping serum and underwent electrophoresis at 30 mamp (2.0 V/cm for 1.5 hours). Detection of GBS antigen was attempted in serum, CSF, urine, or concentrated urine after centrifugation using LA and CIE.

Gram-Positive Cocci in Gastric Aspirate

This group included neonates with a maternal history of fever, rupture of membranes of more than 24 hours, foul-smelling amniotic fluid, hyperthermia, hypothermia, apneic spells, hypotension, meconium

aspiration, or tachypnea. Thirty met previously described criteria for RDS.[8-11] Blood cultures, and when indicated, CSF cultures were performed on all neonates. All had a gastric aspirate obtained in the first six hours of life that was Gram's stained and cultured. All with respiratory distress had a chest roentgenogram. A diagnosis of a bacterial infection was made on the basis of a positive blood and/or CSF culture.

Apnea and/or Hypotension

To determine if the finding of nonterminal apnea and/or hypotension was more commonly found in neonates with early-onset GBS pneumonia than RDS, all 19 neonates with early-onset GBS pneumonia and 100 consecutive neonates with RDS were monitored and the findings of nonterminal apneic episodes and/or hypotension in the first 24 hours of life were recorded. Early-onset GBS pneumonia was defined as an illness in neonates less than 8 days old with respiratory distress, a chest roentgenogram positive for infiltrates or having a "ground glass" appearance, and a blood and/or CSF culture containing GBS. Respiratory distress syndrome was defined by previously described clinical and laboratory criteria[8,11] and as having a sterile blood culture. Continuous monitoring was performed for nonterminal apneic spells, defined as being greater than 20 s in duration. Hypotension was defined as a blood pressure of less than or equal to 40 mm Hg by the Doppler technique and checked for at least hourly.

RESULTS

Antigen Detection

A population of 34 neonates with GBS infection was tested. Sixteen had early-onset GBS pneumonia (including two with meningitis), seven had early-onset meningitis and/or sepsis, and 11 had late-onset meningitis and/or sepsis. Eighty percent of these neonates had multiple body fluids tested and 95% of the body fluids were of sufficient volume to test both by LA and CIE. The results were divided into the clinical categories, early-onset pneumonia, all early-onset disease, and late-onset disease and subdivided into antigen detected in body fluids obtained 0 to 12 hours after onset of illness or overall in the first 48 hours after onset of illness (Fig 1 to 3). Since all neonates did not have the same samples collected, the results could not be compared statistically but could be discussed in general terms.

Overall, LA appeared more sensitive than CIE in detecting antigen in body fluids. Latex agglutination detected antigen in 100% of 18 neonates with urine available for concentration. In all disease categories using LA or CIE, concentrated urine was the best body fluid to use to detect antigen. This was followed by urine, then CSF in patients with meningitis and then sera. The percent of body fluids containing GBS antigen was essentially the same in the first 12 hours of illness as in the first 48 hours of illness.

Only eight gastric aspirates (from GBS pneumonia patients) containing GBS by culture were available for antigen testing. Three contained antigen detectable by CIE. Latex agglutination could not be used on gastric aspirates due to their viscosity. Increased in vitro sensitivity of LA over CIE was demonstrated using broth cultures of GBS types 1a, 1b, 1c, 2, and 3. Using the Atlantic or the Burroughs Wellcome GBS antibody, GBS antigen could be detected in the broths to a 1:4 dilution by CIE and to at least a 1:256 dilution by LA. These two antibody preparations gave similar results in the LA and CIE test. The specificity of the two tests was demonstrated in that no GBS antigen was detected in 49 patients infected with bacteria other than GBS, 40 not infected with bacteria, and four only colonized with GBS.

Gram-Positive Cocci in Gastric Aspirate

Of the 109 neonates with respiratory distress or suspected infection tested, 29 neonates had Gram-positive cocci in their gastric aspirates. Their gastric aspirate cultures showed that 17 were GBS, seven α-hemolytic streptococci (*Str pneumoniae*, *Str viridans*, enterococcus or group D *Streptococcus*), one *Staphylococcus epidermidis*, one *Sta aureus*, and three sterile aerobically. Of these 29 neonates, ten had or developed early onset GBS pneumonia and bacteremia, one had GBS meningitis, two had GBS bacteremia, and 1 had *Sta aureus* sepsis. In all cases, the organism from the blood or CSF was the same as that grown from the gastric aspirate. Three neonates in whom RDS developed had α-hemolytic streptococci in their gastric aspirates.

Eighty neonates had no Gram-positive cocci found in their gastric aspirate Gram's stain. Of this group, three gastric aspirate cultures were positive, all GBS. Of these three, GBS pneumonia and bacteremia developed in two and GBS pneumonia and meningitis developed in one. Respiratory distress syndrome developed in 27 neonates who had negative gastric aspirate Gram's stains.

Overall, in 109 neonates with suspected infection or RDS, systemic infectious diseases developed in 14 of 29 (48%) neonates with Gram-positive cocci in their gastric aspirates with these organisms. Early onset GBS disease developed in 13 of the 29 neonates with Gram-positive cocci, ten with early onset pneumonia. Ten of 13 neonates (77%) with early onset GBS pneumonia had Gram-positive cocci in their gastric aspirates, whereas only three of 30 neonates (10%) with RDS had Gram-positive cocci. This difference is highly significant ($P \leq .001$). The clinical significance of culturing GBS from the gastric aspirate in this high-risk group of 109 neonates is demonstrated in that systemic GBS infection developed in 16 of 20 (80%) with GBS in the gastric aspirate.

Apnea and/or Hypotension

Apnea and/or hypotension in the first 24 hours of life were noted in 16 of 19 (84%) of the cases with early onset GBS pneumonia and in 64 of 100 (64%) with RDS. The findings were examined for statistical significance by the χ^2 test. These results were not significantly different ($P > .05$).

COMMENT

Our study demonstrated the usefulness of LA to detect GBS antigen early in the course of early-onset pneumonia, meningitis, and other early- and late-onset GBS infections caused by all types of GBS. Antigen was demonstrated in many samples of sera, CSF, and urine and in all samples of concentrated urine from GBS infected patients. Latex agglutination is rapid, taking three minutes to perform, and is simple to perform.

Edwards et al[7] have previously reported detecting GBS antigen in CSF from patients with GBS type 3 meningitis using LA.

Using CIE, our results confirmed those of Shackelford and Stechenberg[4] who noted that 71% of the cases overall had detectable antigen by 48 hours of illness; 42% had antigen in serum, 70% with meningitis had antigen in CSF, and 93% had antigen in concentrated urine. Siegel and McCracken[5] have noted antigen in body fluids of 14 of 16 (84%) of neonates with GBS meningitis and in three of four (75%) with neonatal bacteremia at the time of diagnosis of the illness vs eight of 13 (61%) and one of three (33%) in our study. These differences may be due to the CIE methodology used, the use of grouping antibody that is less sensitive than type-specific antibody, the patient population studied, or the samples available for testing. In a study of seven neonates with GBS septicemia, Edwards and Baker[6] detected antigen by CIE in the serum of three, urine of three, and concentrated urine of six also emphasizes the value of concentrating urine.

In both our study and that of Edwards et al,[7] LA was more sensitive than CIE. No false-positive results were noted by CIE or LA. As GBS type 3 and *Str pneumoniae* type 14 share a similar capsular polysaccharide, a cross reaction might be noted by these tests.[13] Edwards et al noted one such cross reaction in CSF of a patient with *Str pneumoniae* meningitis type unknown. When using LA, samples must be centrifuged to remove particulate matter that may cause false-positive reactions.

Ablow et al[8] noted four of four cases of GBS pneumonia and zero of one with pure RDS had Gram-positive cocci in the gastric aspirate. Boyle et al[3] noted a positive gastric aspirate Gram's stain in three of three neonates with GBS pneumonia. Our studies confirm that this is a useful test, with 77% of the neonates with early-onset GBS pneumonia and only 10% of the patients with RDS having Gram-positive cocci in their gastric aspirates. Also, in the newborn patients clinically suspected of being infected, there was a 12-fold increased risk of those with Gram-positive cocci in their gastric aspirate developing severe early-onset GBS disease over those without cocci. A similar high risk has been noted if Gram-positive cocci are seen in a tracheal aspirate.[12] There were no cases of *Str pneumoniae* disease. *Streptococcus pneumoniae* could be confused clinically and on Gram's stain with GBS disease as was the *Sta aureus* case in this study.

Ablow et al[8] also noted that apneic spells and/or subjective feelings of shock consisting of mottling, peripheral pallor, and weak pulses were more compatible with GBS pneumonia (seven of eight) than RDS (zero of nine). In our study testing a larger number of patients, apnea and/or hypotension was commonly found in both early-onset pneumonia (84%) and RDS (64%) making this characteristic of little use in distinguishing between these illnesses. A similar finding was reported by Menke et al.[9]

Myocardial Infarction in the Neonate With Normal Heart and Coronary Arteries

MAJ Howard Kilbride, MC, USA; MAJ Gerald L. Way, MC, USA; LTC Gerald B. Merenstein, MC, USA; Jonathan M. Winfield, MB, ChB, FRCP(C)

• Myocardial infarction is rarely recognized in the newborn. We report two cases in which the infant had a normal heart with normal coronary arteries. A review of previously described cases suggests that the most frequent cause of neonatal myocardial infarction is coronary artery occlusion secondary to paradoxical thromboembolization. It is speculated that infarction also can result from coronary hypoperfusion in asphyxiated infants. This report serves to remind the clinician that myocardial infarction can occur in the neonatal period and that an ECG should be obtained when evaluating a newborn with acute onset of shock.

(*Am J Dis Child* 134:759-762, 1980)

Myocardial infarction in the newborn is extremely uncommon. We report two new cases and review the previously reported cases[1-13] in an effort to better define the clinical spectrum and causes of neonatal myocardial infarction.

REPORT OF CASES

CASE 1.—A 2,960-g female infant was born after an uncomplicated 42-week gestation and a normal vaginal vertex delivery. Apgar scores were 9 and 10 at one and five minutes, respectively. The nursery stay and subsequent course at home were uneventful until the morning of admission on the 13th day of life, when the baby cried out, "as if in pain" and became acutely cool and pale. The infant was moribund and ashen. Her pulse rate was 170 beats per minute with a regular rhythm; respirations were 60/min, shallow, and gasping. Peripheral pulses were not palpable and blood pressure was unobtainable. There was no heart murmur or hepatosplenomegaly. The infant was obtunded with absent deep tendon reflexes and only minimal response to pinprick. Arterial blood measurements: fractional concentration of oxygen in inspired gas [FIo_2] 1.00: pH, 6.96; $Paco_2$, 45 mm Hg; Pao_2, 57 mm Hg. The initial chest roentgenogram showed a normal heart size with diminished pulmonary markings. Cardiomegaly and increased pulmonary markings were present on the follow-up chest roentgenogram three days later. The CSF, blood, and urine bacterial cultures and nasopharyngeal and stool viral cultures yielded no growth. An ECG five hours after the onset of pallor was interpreted as consistent with an acute inferolateral myocardial infarction (Fig 1). The creatinine phosphokinase (CPK) and lactic dehydrogenase (LDH) levels 24 hours after the initial presentation were 937 IU/L and 8,700 IU/L, respectively (normal, 5 to 30 IU/L and 40 to 120 IU/L, respectively), and both returned to normal values at the end of one week. Left ventricular dilation and poor left ventricular function was evident on echocardiogram.

The infant was intubated. Intermittent mandatory ventilation was instituted. Persistent hypotension and peripheral vasoconstriction were treated with supplemental fluids, dopamine, and isoproterenol. Sodim bicarbonate and tromethamine were used to correct the metabolic acidosis, and digitalis was begun. The subsequent hospital course was complicated by right-to-left shunting through a patent ductus arteriosus, which resolved with improvement in left ventricular function and increased systemic blood pressure. The baby had seizures on the second hospital day, presumed secondary to cerebral edema and hypoxemia. Cardiac catheterization was performed two weeks after initial examination and demonstrated normal coronary arteries without evidence of occlusion. The left ventricular function was diminished, and there was a dyskinetic lateral segment. One month after hospitalization, the baby appeared normal without evidence of congestive heart failure. The ECG findings showed improvement (Fig 2). Diminished left ventricular function remained evident on echocardiogram.

CASE 2.—A 3,440-g, term, appropriate for gestational age female infant was born by elective cesarean section (indication: previous cesarean section. Apgar scores were 4 and 1 at one and five minutes, respectively. The infant was intubated and given a plasma expander for hypotension. The initial arterial blood measurements were (FIo_2, 1.00): pH, 6.92; Pao_2, 33 mm Hg; $Paco_2$, 77 mm Hg. On admission, the temperature was 37.5 °C, pulse rate was 150 beats per minute, and respirations were 65/min. The blood pressure was 100/40 mm Hg, although the infant did not appear well perfused. She was obtunded and responded only to painful stimuli.

A chest roentgenogram showed a large cardiothymic shadow and possible pulmonary vascular congestion. An ECG at 6 hours of age was interpreted as consistent with an inferolateral myocardial infarction (Fig 3). Diminished left ventricular function was evident on echocardiogram.

Despite therapy, the patient had persistent hypoxemia and a combined respiratory and metabolic acidosis. A 30-mm Hg difference in Pao_2 between right radial and umbilical artery catheter blood gas levels was noted. Administration of tolazoline, epinephrine, and isoproterenol resulted in no clinical response. The infant died at 29 hours of age.

At autopsy, the heart weighed 22.8 g. Grossly, the free wall of the left ventricle was soft to palpation and had a dark red discoloration consistent with an acute myocardial infarction. The foramen ovale was probe-patent and the ductus arteriosus was widely patent. The coronary arteries were anatomically normal, and all branches were patent without evidence of thrombi. The umbilical vein and ductus venosus were free of thrombi. The lungs appeared consolidated. The rest of the gross examination findings were within normal limits.

Microscopic examination of the sections of the left ventricle revealed massive

hemorrhage and necrosis. Serial sections of the coronary arteries were examined and revealed no intimal changes or thrombi.

COMMENT

Although myocardial infarction in the newborn is rarely recognized, two cases are reported herein in which the diagnosis was made early in the clinical course. Each infant manifested peripheral cardiovascular collapse and a persistent metabolic acidosis. The ECG in both cases had Q waves and T-wave inversions consistent with myocardial injury. In case 2, the diagnosis of myocardial infarction was confirmed by postmortem findings. Patient 1 survived and, therefore, there was no tissue examination. Although similar ECG and enzyme changes may be seen in myocarditis, and although this possibility cannot be completely ruled out, the failure to isolate an infectious agent and the clinical findings favor the diagnosis of myocardial infarction in our patient. Extreme elevations of CPK and LDH levels suggest that, in addition to myocardial necrosis, widespread tissue injury occurred, most likely secondary to the marked hypoxemia and hypotension.

Myocardial infarction in the newborn is usually seen in association with congenital heart disease, specifically, obstructive lesions (ie, aortic stenosis),[14,15] anomalous origin of the left coronary artery,[16] and tricuspid atresia.[17] It also has been described in association with hematologic abnormalities.[18,19] Myocardial infarction in older infants has been recognized secondary to degenerative and inflammatory disease of the coronary arteries.[15] In the absence of an underlying systemic disorder or anatomical abnormality, neonatal myocardial infarction is unusual, and, to our knowledge, only 13 previous cases have been reported.[1-13] The condition was diagnosed in eight ante mortem.[4-9,11-12]

The clinical manifestations of our two patients are similar to those previously reported.[1-13] As demonstrated by these 15 cases, neonatal myocardial infarction must be considered in a newborn who has an acute onset of shock and a severe metabolic acidosis. Neonatal myocardial infarction may be complicated by right-to-left shunt-

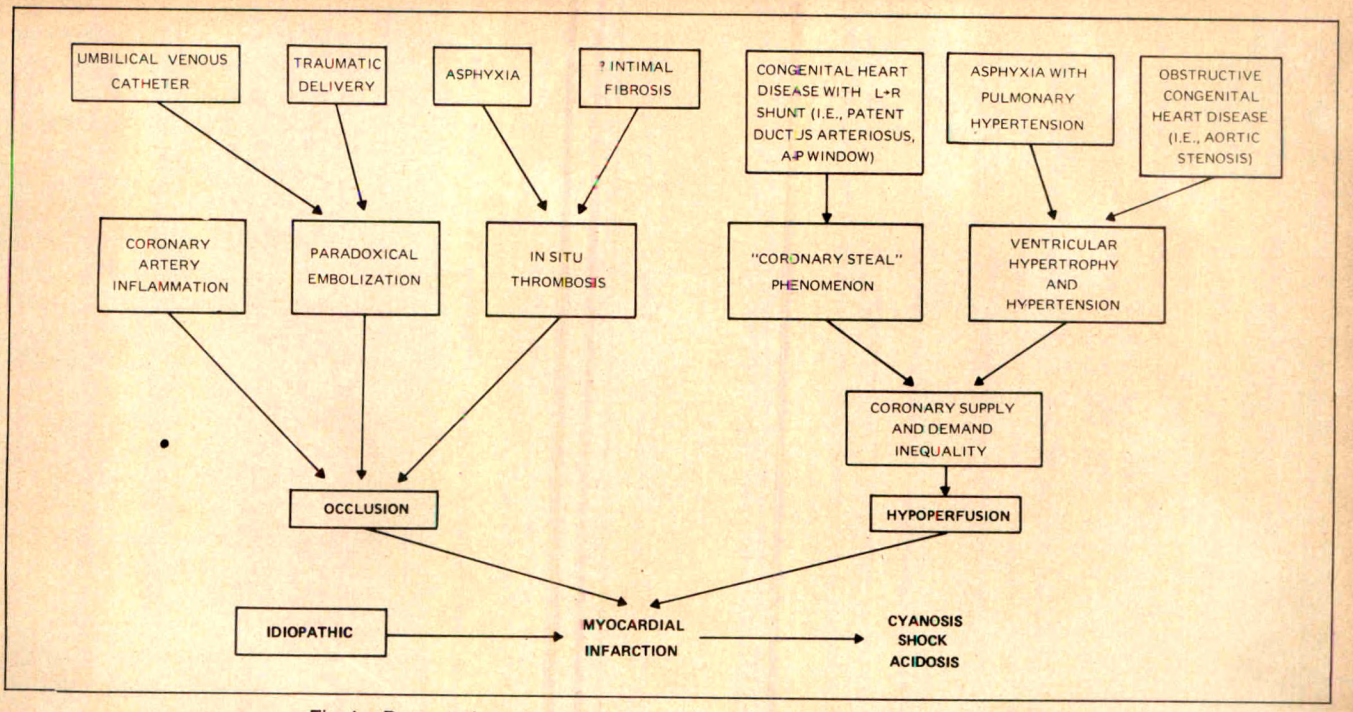

Fig 4.—Proposed mechanisms leading to neonatal myocardial infarction.

ing through a patent ductus arteriosus, a situation that may initially mimic persistent pulmonary hypertension of the newborn. Recognition of the correct diagnosis is imperative prior to therapeutic intervention, as use of tolazaline in an infant with ventricular dysfunction may accentuate systemic hypotension and increase right-to-left shunting.

Although there are several diagnostic considerations that the clinician must exclude when presented with a newborn in shock, an ECG can accurately diagnose myocardial injury if it is present. Of the reported cases of myocardial infarction, 12 had an ECG obtained as part of their evaluation. The initial ECG abnormalities were specified in 11, and of these, nine demonstrated Q waves and ST-T wave changes in the anterior, inferior, and lateral leads. Contrary to the usual initial ECG findings of ST elevation in adults with myocardial infarction,[20] only two infants had ST segment changes alone on their ECGs.[6,9]

The ECG changes may be initially misinterpreted. Deep Q waves in the lateral precordial leads with diminished or absent left-sided forces may suggest the hypoplastic left heart syndrome, but this diagnosis may be ruled out by echocardiogram.[13] A myocardial injury pattern on the ECG may also be initially misinterpreted as type B Wolff-Parkinson White syndrome.[10] However, Q waves and ST-T wave changes in conjunction with the clinical setting of shock and acidosis in the newborn should make the clinician suspect a myocardial infarction.

There are several possible causes of myocardial infarction in the newborn. Coronary thrombosis has been reported twice.[4,13] Gault and Usher[4] described an infant with coronary artery thrombosis associated with focal intimal thickening. They stated that although thrombosis is unusual, intimal changes are frequent findings in newborns without heart disease. Moon[21] has suggested that intimal proliferation may reflect tissue reaction to a perinatal asphyxial insult, and he reported that the histologic changes were identical to those seen in the early phases of arteriosclerosis in adults. These intimal changes have not been noted in other reported cases of neonatal myocardial infarction.

The most frequent cause of neonatal myocardial infarction appears to be embolic injury. One infant had an air embolism apparently secondary to placement of an umbilical venous catheter.[11] Postmortem examinations in six other cases demonstrated a coronary artery thromboembolus,[1,6-9,12] and in four of these, thrombus formation was found in the ductus venosus or in the umbilical vein.[7-9,12] All had a widely patent foramen ovale and/or ductus arteriosus. These findings suggest that infarction occurred secondary to paradoxical thromboembolization, with the thrombus originating in the umbilical venous system. In two cases, the embolization was temporally related to the placement of an umbilical venous catheter. Thrombus formation is commonly associated with such catheters,[22] and was the probable source of the thromboemboli in these two cases. Presumably, in the other four cases, thrombus formed in the ductus venosus or umbilical vein secondary to cord compression or stasis following birth asphyxia. This hypothesis is supported by the fact that the most frequent predisposing factor in all the cases reviewed appeared to be a difficult delivery, often associated with a breech extraction or cord prolapse.

Three of the cases of neonatal myocardial infarction,[2,3,10] in addition to our case 2, had no postmortem evidence of thrombosis or thromboembolization. Therefore, the pathogenesis of infarction in these infants is unclear. It is possible that they could have suffered a coronary occlusion that was not evident at examination because of thrombolysis or clot retrac-

tion. However, since each infant died within hours of infarction (range, nine to 29 hours), one would expect some residual evidence of the thrombus or intimal reactive changes. We believe it is more likely that these infants suffered myocardial injury secondary to impaired coronary artery perfusion. The common denominator for all four of these infants was neonatal asphyxia. Myocardial ischemia, secondary to coronary hypoperfusion, has been described in hypoxic term infants.[23] Rowe and Hoffman[23] have proposed that these infants may have an excessively brisk pulmonary vasoconstrictive response to hypoxia, leading to right ventricular hypertrophy and excessive demands on the coronary arterial supply. Subendocardial ischemia also has been seen in a group of infants who had respiratory distress and a patent ductus arteriosus.[24] It is suggested that the cause of the diminished coronary perfusion in these infants is a "ductal steal" phenomenon.[24] In addition to these examples of myocardial ischemia, there is evidence from postmortem examination of infants dying with congenital heart disease that circulatory disturbances of the coronary arteries can lead to myocardial infarction.[14,17]

While diminished coronary perfusion probably occurs frequently in asphyxiated newborns, transmural infarction would appear to be an unusual consequence.[25] When it does occur, it probably results from a combination of factors, ie, hypoxemia, excessive pulmonary vasoconstriction with ventricular hypertension and increased cardiac work, and perhaps diminished perfusion from a "ductal runoff." A patient in whom the right coronary artery supplies a large portion of the posterior wall of the left ventricle may have an increased susceptibility to several of these factors.[23]

In addition to these mechanisms, coronary spasm, which has been reported as a cause of myocardial ischemia and occasionally infarction in adults,[26,27] also might be suggested as a factor leading to myocardial damage in the newborn. However, myocardial infarction following coronary spasm in adults usually has been reported in patients with severely narrowed coronary arteries.[28] Therefore, it would seem unlikely that coronary spasm by itself would be a significant etiologic factor in myocardial infarction in the newborn. However, it has been demonstrated by angiography in adults that coronary spasm can be precipitated by α-adrenergic agonists.[29] In a stressed newborn with a marked catecholamine response, coronary spasm may, in some cases, accentuate a myocardial hypoperfusion state.

The two pathways for infarction appear to be (1) coronary artery occlusion, and (2) diminished coronary perfusion without occlusion (Fig 4). Case 1 cannot be readily explained by either of the proposed mechanisms. As a result, the cause of the infarction in this case remains unknown.

These case reports serve to remind the clinician that myocardial infarction can occur in an otherwise healthy newborn. An ECG should be obtained when an infant has an acute onset of shock, especially if there is a delivery history consistent with cord compression or asphyxia, or a history of an umbilical venous catheterization.

Frederick Parkhurst, MD, and Harry Laws, MD, referred these cases, and Jan Gerhardy and Cheryl Noles provided secretarial assistance.

The Epidemiology of Poisoning From Drug Products

Michael Saracino; James Flowers; Frederick H. Lovejoy, Jr, MD

• On the basis of 24,487 telephone calls to a poison control center during a one-year period, the 12 most commonly ingested drugs (accounting for 2,417 calls) were selected for study. Each agent was analyzed on the basis of (1) age of the individuals involved, (2) frequency of overdose, and (3) signs, and symptoms, and severity. These findings have implications for the diagnosis and prevention of drug overdose.

(*Am J Dis Child* 134:763-765, 1980)

An awareness of the epidemiology of potentially poisonous substances is useful for the clinician in dealing with acute overdoses.[1-5] By focusing on what is commonly encountered in the clinical setting, greater accuracy in diagnosis and a more rational approach to prevention are possible.

METHODS

In an effort to determine the characteristics of poisoning from prescription and nonprescription medications, information on all telephone calls to a poison control center relating to drug ingestion between July 1977 and June 1978 were analyzed.[6] The information was recorded by poison information specialists, then coded, keypunched, and entered in a computer.

Of 24,487 drug and household product overdoses over the one-year period, the 12 most commonly ingested drugs (representing 2,417 calls) were analyzed in detail. Drug products were defined as chemical compounds available to the public and intended for specific therapeutic effect. Overdoses occurred by the oral, cutaneous, or pulmonary routes. Four age groups were considered for analysis: group 1, 0 to 5 years of age; group 2, 6 to 12 years; group 3, 13 to 20 years; group 4, older than 20 years. Signs and symptoms reviewed included nausea, vomiting, lethargy, dizziness, coughing, choking, dyspnea, ataxia, coma, convulsions, cyanosis, and hypotension. An estimation of severity was determined by the ratio of signs and symptoms to exposures.

RESULTS

Of the 1,975 overdoses in which age of the subject was known, 60% were in group 1, 4% in group 2, 9% in group 3, and 27% in group 4. The frequency of overdose with each of the 12 most common drugs in each age group is presented in Fig 1. In group 1, aspirin was the most commonly ingested drug, followed by vitamins and acetaminophen; in group 2, aspirin, followed by vitamins, isopropyl alcohol, and acetaminophen; in group 3, aspirin, followed by diazepam, acetaminophen, and phencyclidine hydrochloride; and in group 4, diazepam, followed by flurazepam hydrochloride and acetaminophen.

Signs and symptoms occurred in 21% of the overdoses—23% in group 1, 4% in group 2, 22% in group 3, and 51% in group 4. The frequency of signs and symptoms for each of the 12 drug products is presented in Fig 2. In group 1, a combination of brompheniramine maleate, phenylephrine hydrochloride, and phenylpropranolamine hydrochloride (Dimetapp) and aspirin produced the greatest frequency of signs and symptoms; in groups 2 and 3, diazepam and aspirin; and in group 4, diazepam and flurazepam. When severity of the ingestion was considered, based on a ratio of signs and symptoms to exposure for a given product (Fig 2), phencyclidine ingestion was most serious, followed by ingestion of diazepam, a combination of oxycodone, oxycodone terephthalate, caffeine, aspirin, and phenacetin (Percodan), and flurazepam.

Seventy-four percent of the overdoses were accidental, and 26% were purposeful (suicide attempts and drug abuse). Of 1,463 accidental overdoses, 25% were due to aspirin, 16% to vitamins, 12% to acetaminophen, and 10% to isopropyl alcohol. Of 493 suicide attempts, 43% involved diazepam, 13% flurazepam, 12% aspirin, and 11% ace-

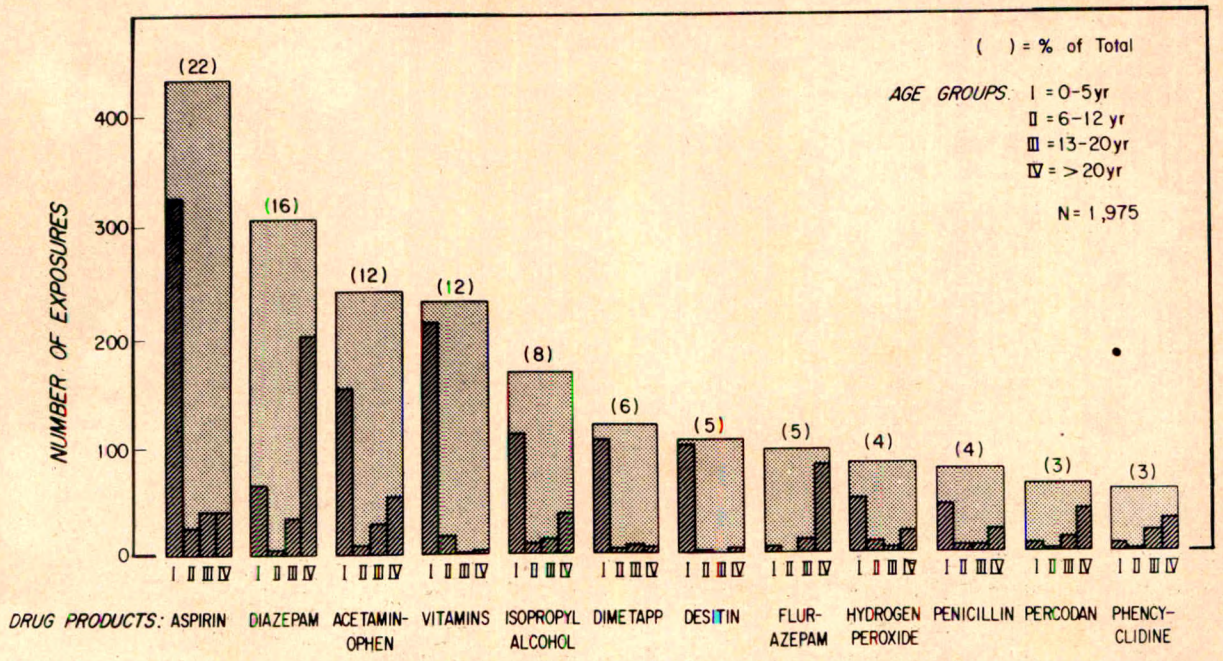

Fig 1.—Descending order of frequency for 12 most common causes of drug overdoses, illustrating number and percentage of exposures for each. Number of exposures in each age group for each drug is illustrated by cross-hatched bars.

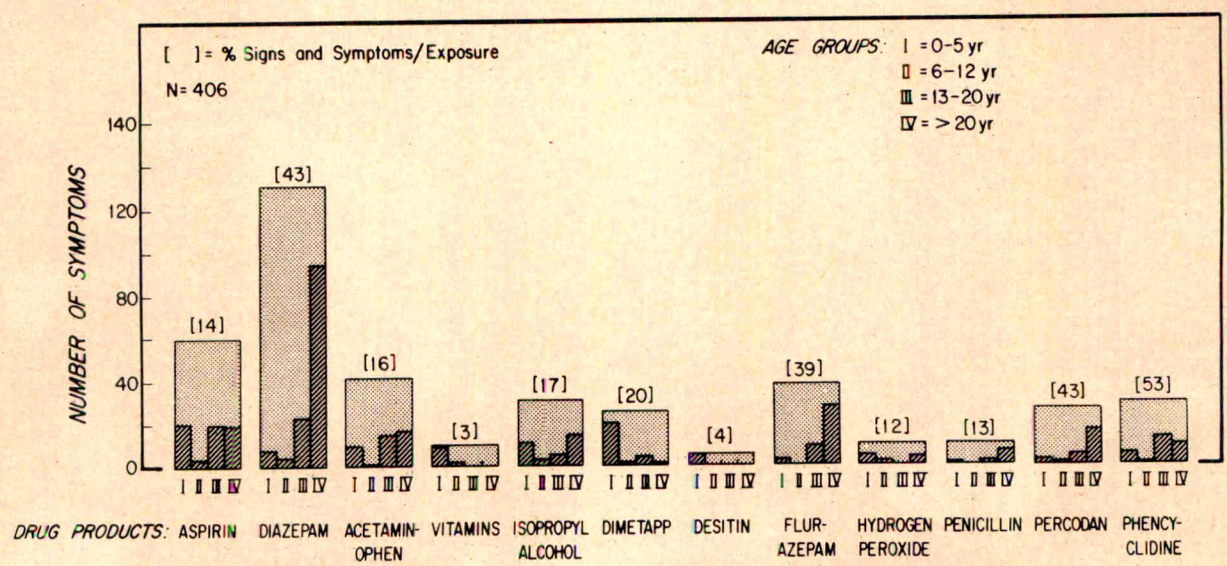

Fig 2.—Frequency of symptoms and relative severity (signs and symptoms per exposures) for 12 most common causes of drug overdoses. Frequency of symptoms in each age group for each drug is illustrated by cross-hatched bars.

taminophen. Phencyclidine was the most commonly abused drug.

COMMENT

This study of the 12 most commonly ingested drugs represented 10% of all calls reported to this poison control center during a one-year period. Children were most likely to ingest drugs for fever (aspirin, acetaminophen), nasal decongestion (Dimetapp), and rash (zinc oxide and cod liver oil combination [Desitin]), as well as vitamins and isopropyl alcohol. Adults were most likely to ingest sedatives (diazepam, flurazepam), analgesic or antipyretic medications (Percodan, aspirin, and acetaminophen), and phencyclidine.

Aspirin and acetaminophen together accounted for 23% of the calls involving suicide attempts (12% and 11%, respectively). In addition, aspirin was the most commonly ingested drug product in groups 1, 2, and 3, while acetaminophen was among those drugs most commonly ingested in all four age groups. Aspirin was the most frequent cause of signs and symptoms in group 1, caused signs and symptoms in equal frequency with diazepam in groups 2 and 3, and was surpassed in frequency only in group 4 by diazepam and flurazepam. These data suggest that continued education—directed not only at children under 5 years of age, but also at the adolescent and adult—is warranted to increase awareness that both aspirin and acetaminophen are associated with substantial risk.

Diazepam and flurazepam were, respectively, the second and eighth most common cause of drug overdose, the first and second most common cause of symptoms, and the second and fourth most severe (signs and symptoms per exposures). Approximately 60% of the suicide attempts involved diazepam and flurazepam. These figures suggest that great care is necessary when prescribing a benzodiazepine to any patient who is prone to self-injury.

Percodan ranked 11th as a cause of drug overdose, fourth as a cause of signs and symptoms, and third in severity. Before prescribing Percodan for analgesia, the risk of overdose or abuse must be carefully considered.

While we found phencyclidine to be the 12th most common cause of drug overdose, it had the second most frequent rate of signs and symptoms and was the most serious as defined by the ratio of signs and symptoms to exposures. The serious nature of phencyclidine toxicity needs to be continually emphasized to the drug-abusing adolescent and young adult.

Vitamins, isopropyl alcohol, Dimetapp, Desitin, hydrogen peroxide, and penicillin are the most common causes of overdose in children aged 5 years and under. Vitamins, Desitin, hydrogen peroxide, and penicillin produced signs and symptoms infrequently when contrasted to the six drugs already discussed. All six drugs remain strong justification for continued poison prevention education focused on the pediatric population.

This study draws attention to the 12 drug products most commonly ingested. It is hoped that these data will serve to increase physician awareness of those drug products of greatest risk and hence lead to improved diagnosis. In addition, consideration of the most common drugs ingested, the age of the patient involved, and the underlying reason for the poisoning are all necessary to carry out effective poison prevention efforts. Finally, the data indicate the need for poison control centers to expand their focus of poison prevention activities to the adolescent and adult, in whom morbidity and mortality are high and the potential gains for new methods of preventing drug abuse and suicide could have considerable impact.

This study was supported in part by grant 01-11-00387-01-0 from the Office of Emergency Medical Services, Massachusetts Department of Public Health.

The Massachusetts Poison Control System is a cooperative effort of the Massachusetts Department of Public Health, Children's Hospital Medical Center, Massachusetts College of Pharmacy, Tufts-New England Medical Center, University of Massachusetts Medical School, and community and teaching hospitals throughout Massachusetts.

Early-onset Sepsis and Pneumonia Observed as Respiratory Distress Syndrome

Assessment of Lung Maturity

Jack Jacob, MD; David Edwards, MD; Louis Gluck, MD

• **Lung maturity was assessed in nine neonates with early-onset sepsis and/or pneumonia first observed as respiratory distress syndrome (RDS). All but one infant had at least one clinical or laboratory feature in the immediate postnatal period that suggested infection. Five patients had a mature phospholipid pattern in tracheal or gastric secretions, suggesting that RDS was not present; four patients had an immature pattern, suggesting that RDS coexisted with early-onset sepsis and/or pneumonia. Neither clinical nor radiologic features differentiated patients whose surfactant phospholipid patterns were mature from those whose patterns were immature. The presence of a mature surfactant complex in an infant with RDS should suggest the presence of infection. The presence of an immature pattern, however, does not exclude the presence of infection since RDS may coexist with early-onset sepsis and/or pneumonia.**

(*Am J Dis Child* 134:766-768, 1980)

Recently, it has been recognized that sepsis and pneumonia with group B streptococcus (GBS), *S pneumoniae*, *S bovis*, and *Haemophilus influenzae* may have clinical features similar to respiratory distress syndrome (RDS) of the newborn.[1-5] There have been several brief reports on the status of lung maturity in patients with RDS due to early-onset GBS sepsis.[6-8] All but one of these reports[8] have suggested that patients with GBS sepsis have mature values for pulmonary surfactant, as assessed by the "shake test" on gastric aspirate[7,8] or by the phospholipid composition of tracheal aspirate.[6] The present study reports on the phospholipid composition of the tracheal or gastric aspirates of nine newborn infants with early-onset sepsis and/or pneumonia first observed as RDS and correlates these with clinical and radiological findings.

California Medical Center, San Diego, between September 1977 and June 1979. All patients with early onset of sepsis and/or pneumonia (within the first few hours of life) mimicking RDS, both clinically and radiologically, were included in this report. Patients with early onset of sepsis but with a normal chest roentgenogram or one displaying obvious pneumonia (focal infiltrates or consolidation) were excluded because a diagnosis of RDS was not considered. Clinical records were reviewed retrospectively. Chest roentgenograms were read without knowledge of clinical history.

Surfactant Maturity Studies

Gastric aspirates were collected after birth; tracheal aspirates were collected by routine suctioning of each infant during the first 24 hours of life. If the amount of lipid in the tracheal secretions was inadequate, material from several tracheal aspirates obtained in the first 24 hours were combined. Lipid extraction was performed by a modification of the technique by Bligh and Dyer,[9] using chloroform and methanol (2:1, v/v). Phospholipids were separated after cold acetone precipitation (which concentrates the disaturated lecithin) by two-dimensional thin-layer chromatography as described previously.[10] Both acetone-precipitable and acetone-soluble fractions were spotted separately and run in parallel in the first dimension (solvent: chloroform-methanol-water-glacial acetic acid [65:24:4:8, v/v/v/v]). The acetone-precipitable (disaturated) fraction was run in the second dimension perpendicular to the first run after drying at 70 °C for five minutes (solvent: tetrahydrofuran-methyla1-methanol-2*N* ammonium hydroxide [40:28.5:7.8:4.2, v/v/v/v]). This technique separates highly saturated lecithin and other phospholipids, including sphingomyelin, phosphatidylserine, phosphatidylinositol (PI), phosphatidylethanolamine, and phosphatidylglycerol (PG), that are present in the acetone-precipitable fraction; the acetone-soluble fraction principally contains unsaturated lecithin. Individual phospholipids were quantified by reflectance densitometry, expressed as percentage of total phospholipid in the acetone-precipitable fraction. In addition, the lecithin-sphingomyelin (L/S) ratio and the percent of total lecithin precipitated by cold acetone were also calculated as previously described.[11]

RESULTS

Clinical and laboratory data on the nine patients are outlined in the Table. The diagnosis of sepsis and/or pneumonia was made in all but one patient by culturing the appropriate organism from the blood and other sources. A single patient (No. 5), who had been treated with antibiotics prior to obtaining appropriate cultures, had a tracheal aspirate positive for GBS by the technique of counterimmunoelectrophoresis. None of the patients had meningitis. The organisms identified were GBS, *H influenzae*, *S pneumonia*, and *Escherichia coli*. Although only one patient (No. 6) had a prenatal history suggesting infection, all but one infant (patient 1) had at least one clinical or laboratory finding in the immediate postnatal period suggesting its presence. Early onset of shock and leukopenia was frequently correlated with the presence of infection. When done, a Gram's smear of the gastric aspirate showing large numbers of Gram-positive cocci also was helpful in detecting GBS infection. Thrombocytopenia was evident only after the first day of life.

Radiologic features suggesting RDS[12] were present in all cases on the initial roentgenogram obtained within the first few hours of life. These included fine, diffuse granularity (eight cases), air bronchograms (seven cases), and/or symmetrical, homogeneous involvement of both lungs (seven cases). Cardiomegaly, which has been described as a frequent feature of

*GBS indicates group B streptococcus; CIE, counterimmunoelectrophoresis; L/S, lecithin-sphingomyelin.
†The WBC count was < 10,000/cu mm.

GBS,[13] was noted in only one patient. Underaeration, which is usually seen in cases of RDS, was noted in only two patients. The most consistent feature suggesting infection[14] was the presence of pleural fluid in areas other than the fissures (apices and costophrenic angles); this was noted in seven cases. All patients demonstrated at least one feature not typical for uncomplicated RDS.

Five patients had a mature surfactant phospholipid pattern, while four patients had an immature pattern usually found in RDS.[15,16] Patients with mature patterns in tracheal aspirates had higher L/S ratios; greater amounts of acetone-precipitable (primarily disaturated) lecithin; and the presence of PG or, if absent (as in patient 2), a relatively large amount of PI.

The presence of PG in amniotic fluid or tracheal aspirates excludes the diagnosis of RDS.[15,17] In the absence of PG, a relatively large amount of PI (>20%) with a high L/S ratio and a large amount of disaturated lecithin also suggest that RDS is absent.[17]

The only clinical features that distinguished patients with a mature tracheal phospholipid pattern from those with an immature pattern were birth weight and degree of maturity; all infants with a mature pattern weighed ≥1,900 g and were of ≥34 weeks' gestation. Neither age at onset nor duration of respiratory distress were different in patients with a mature surfactant phospholipid pattern compared with those with an immature pattern. In addition, chest roentgenograms were similar in both groups of patients.

COMMENT

Although all infants in this report had clinical and radiologic findings similar to those seen in RDS, certain features of their illness (shock, apnea, leukopenia, etc) suggested the presence of infection. This has been previously noted by Ablow et al[18] in early-onset infection with GBS. Also, all patients had chest roentgenograms that were to some extent atypical of RDS and that suggested coexistence of pneumonia.[14,19]

Saunders et al[6] found a mature phospholipid composition of tracheal aspirates in three term infants with early-onset GBS sepsis. Tanswell and Smith[7] and Lewins[8] described a total of seven premature infants with early-onset GBS sepsis who had abnormal "shake tests," suggesting surfactant maturity. Two additional extremely immature infants (27 weeks' gestation) described by Lewins[8] had normal "shake tests," suggesting these infants also had RDS.

Analysis of phospholipids in gastric and tracheal aspirates on the first day of life in the nine patients described here demonstrated that five patients had mature patterns, suggesting that RDS was not present. An additional four patients had immature phospholipid patterns in their tracheal aspirates, suggesting that RDS coexisted with early-onset sepsis and/or pneumonia. Neither the clinical and radiologic presentation nor the outcome differentiated patients whose surfactant phospholipid patterns in tracheal aspirates were mature from those whose were immature. However, the five patients with mature phospholipid patterns were more mature on the basis of estimated gestational age than those with immature phospholipid patterns. Since complete surfactant maturity normally may occur as early as 34 to 35 weeks' gestation,[17] the presence of a mature surfactant complex in these infants may be due to their relatively advanced gestational age.

It has been suggested[7] that an abnormal gastric aspirate "shake test," suggesting maturity of surfactant in a patient with respiratory disease simulating RDS, should be an indication to search for a source of infection and the institution of antibiotic therapy. The presence of a mature phospholipid complex in some of our patients confirms such a recommendation. However, our results suggest that an immature pattern suggesting RDS in preterm infants does not exclude the coexistence of early-onset sepsis and/or pneumonia.

This investigation was supported in part by Public Health Service grants HD10622 and HD05571.

The Diagnosis of Phenylketonuria

A Report From the Collaborative Study of Children Treated for Phenylketonuria

Margaret E. O'Flynn, MB, ChB; Neil A. Holtzman, MD; Milan Blaskovics, MD; Colleen Azen; Malcolm L. Williamson, PhD

• One hundred ninety-five infants who met diagnostic criteria for enrollment in the Collaborative Study of Children Treated for Phenylketonuria (PKU) underwent a standard three-day challenge with 180 mg/kg/day of phenylalanine for confirmation of diagnosis. A sustained rise in serum phenylalanine levels of greater than 20 mg/dL was observed in 166 infants (85.1%), compatible with the diagnosis of classical PKU. In the remaining 29 infants (14.9%), the serum phenylalanine concentration either did not reach 20 mg/dL or, having achieved this level, subsequently declined below this point by 72 hours. It was agreed that these 29 patients had variant PKU and they were dropped from the Collaborative Study. We recommend that all infants diagnosed as having classic PKU undergo a challenge to confirm the diagnosis and need for continued treatment.

(*Am J Dis Child* 134:769-774, 1980)

Phenylketonuria (PKU), an inborn error of metabolism, is characterized in the untreated state by mental retardation and the presence of phenylpyruvic acid in the urine, as described initially by Fölling in 1934.[1] Other workers[2,3] later demonstrated that the serum phenylalanine level was persistently elevated above 15 to 20 mg/dL and that, in addition to phenylpyruvic acid, phenylalanine and its metabolites, particularly orthohydroxyphenylacetic acid (o-HPAA) are found in the urine in greatly increased quantities. These biochemical criteria have been generally accepted as the basis of the diagnosis of classic PKU.

Since the development of newborn screening programs for detection of PKU, a population of variant infants with persistent hyperphenylalaninemia has been identified.[4-6] Biochemically, variant individuals are characterized by serum phenylalanine levels generally below 20 mg/dL, but in the newborn period levels ranging from 20 to 30 mg/dL or higher[4,7] have been observed. The amount of phenylalanine metabolites found in the urine varies considerably, usually reflecting the serum phenylalanine level. Phenylpyruvic acid may be either undetectable or present in large quantities, while o-HPAA is found in moderately increased amounts. The incidence of the PKU variant has been estimated at 1:17,000, and the ratio of variant to classic PKU appears to be almost 1:1 in North America.[8]

Prevention of mental retardation in classic PKU may be achieved by institution of a low phenylalanine diet in early infancy, preferably no later than 2 months of age.[9] Clinically, the variant population follows a normal pattern of intellectual development while receiving a normal diet; restriction of phenylalanine intake not only is of no proved benefit to these individuals,[10,11] but may be hazardous to their physical and mental development when inappropriately prescribed.[12] Reported complications associated with the phenylalanine-restricted diet include anorexia, anemia, hypoproteinemia, and hypoglycemia,[13] and it is therefore critically important that all infants with hyperphenylalaninemia be carefully evaluated before committing them to long-term therapy. It is generally agreed that infants with serum phenylalanine levels above 20 mg/dL should be given a phenylalanine-restricted diet, with some centers recommending 15 mg/dL as the appropriate level at which to start treatment.

The biochemical overlap between variant and classic PKU patients is substantial, making differential diagnosis difficult. Attempts to distinguish between the two groups have concentrated on differing responses to a standard load of phenylalanine. The phenylalanine tolerance test developed by Hsia et al[14] to detect the heterozygote state has not been found to be reliable for this purpose, but when phenylalanine is given in the form of a balanced protein load (such as evaporated or whole milk) over an extended period, the two groups can be distinguished[15] by evaluation of the change in serum phenylalanine level observed during the test period. Relatively few individuals have been found to be unclassifiable using this method.[7]

In 1967, the Collaborative Study of Children Treated for Phenylketonuria, representing 19 PKU clinics, began a controlled prospective study to determine the effects of treatment on classic PKU.[16] It was imperative that a pure sample of PKU patients uncontaminated by variant individuals be entered into the study, and accordingly the following criteria were proposed and adopted: (1) Serum phenylalanine levels must have reached or exceeded 20 mg/dL on at least two occasions 24 hours apart while the patients ingested a normal diet for age; (2) serum tyrosine levels, on two specimens obtained at the same time as those for phenylalanine determinations, must have been recorded as no higher than 5.0 mg/dL; and (3) the urinary metabolites found in classic PKU, such as o-HPAA and phenylalanine itself, must have been present in excess.

As the possibility existed that some variants would meet these criteria initially, the protocol called for confirmation of the diagnosis of all subjects

From the Collaborative Study of Children Treated for Phenylketonuria. For a complete list of project staff and participating clinics, see p 744.

three months after tentative diagnosis and initiation of treatment by means of a standardized challenge procedure.[17] If, in response to the challenge, the serum phenylalanine level exceeded 20 mg/dL for 24 hours or longer and the urine at that time contained increased amounts of the metabolites found in classic PKU, the subject was considered to have true PKU and continued in the treatment phase of the study at the discretion of the clinic director.

The purpose of this report is to describe the experience of the Collaborative Study of Children Treated for Phenylketonuria in using these criteria for the diagnosis of PKU.

PATIENTS AND METHODS

Biochemical Studies

All serum phenylalanine determinations were performed by means of the McCaman-Robins[18] fluorometric method. Serum tyrosine levels were determined by the fluorometric method of Waalkes and Udenfriend.[19] Aliquots of samples obtained at the time of diagnosis and phenylalanine challenge were sent to the Serum Reference Laboratory at the University of Southern California, Los Angeles, for comparability of results of serum phenylalanine and tyrosine. Urine collected at the times of diagnosis and challenge was acidified to pH 1.8 ± 0.2 and sent to the Chromatographic Reference Laboratory at the same institution for determination of creatinine, phenolic acid, and ferric chloride levels and two-dimensional paper chromatography for phenylalanine metabolites. (Variations above and below mean values are SDs, not SEMs.)

Phenylalanine Challenge

Three months after institution of therapy, the need for continuation of the restricted diet was evaluated by means of a natural protein challenge. This procedure involved discontinuation of the low phenylalanine (Lofenalac) diet; in its place, 720 mL of whole milk or 360 mL of evaporated milk diluted with 360 mL of water was given every 24 hours. After experience, the amount of milk offered was adjusted individually to provide an intake of 180 mg/kg/day of phenylalanine for each infant. The milk was offered in frequent small feedings spaced throughout the day to minimize loss by emesis. Water intake was encouraged during the challenge period. A high-carbohydrate, nonprotein supplement (Dextri-Maltose), was used freely to ensure a good caloric intake. The challenge was performed only when the infant was in good health, since even minor illnesses may cause elevations in serum phenylalanine levels, thus potentially leading to misdiagnosis.

The protocol required that the challenge be continued for 48 to 72 hours. For the first years of the study, serum phenylalanine values were usually obtained only at the end point. However, as experience with the procedure was gained, determinations were requested at intervals of 24 ± 4 hours and the challenge was extended to 72 hours.

Initially, if the serum phenylalanine level was known with certainty to exceed 20 mg/dL prior to 72 hours, it was considered acceptable to discontinue the challenge early. Two urine samples were collected for determination of phenylalanine and metabolites—the first prior to and the second at 60 to 72 hours after the initiation of the procedure.

For those patients in whom the challenge was delayed beyond infancy, frequently because of intercurrent illness at the time the challenge was scheduled, a similar protocol was followed using phenylalanine (L-phenylalanine) as an alternative to natural protein. It was suggested that the ingestion of large quantities of natural protein by older children over a three-day period might be unpredictable. No change was made in the basic dietary prescription, but the phenylalanine content of the diet was increased to 180 mg/kg/day by the addition of phenylalanine to the low phenylalanine formula in calculated amounts. Blood and urine samples were obtained as already described.

Patient Selection

Infants admitted to the Collaborative Study were born between Oct 1, 1967, and Sept 30, 1972, in states with newborn screening programs for detection of PKU. In addition to meeting the biochemical criteria listed in an earlier section, it was required that infants be less than 120 days of age at the time of entry. The protocol was discussed with parents, and informed consent was obtained prior to enrollment of their child in the study.

RESULTS

Two hundred twenty-four infants entered the project as index patients. All but eight of these met study criteria, giving a total of 216 infants—124 boys and 92 girls—formally enrolled. Most of the infants were born at term (only 8.8% of the 182 infants for whom gestation was recorded being born at less than 38 weeks' gestation); 96.8% were white, and 49.6% were first-born.

Initial Data

Serum biochemistry determinations were obtained for 216 infants on entry to the study, when their mean age was 20.7 ± 14.5 days. The serum phenylalanine levels ranged from 20.7 to 98.4 mg/dL, resulting in a mean value for the group of 45.1 ± 14.8 mg/dL.

Data on serum tyrosine levels were available on 193 subjects (89.4%), the mean value being 2.4 ± 1.1 mg/dL. Individual values ranged from 0.6 to 6.7 mg/dL. Six infants had levels above 5 mg/dL; subsequently, however, the levels declined to below 5 mg/dL. One infant of 36 weeks' gestation was initially thought to have transitory neonatal tyrosinemia, and the diagnosis of PKU was made when the serum tyrosine level was noted to decline whereas the phenylalanine level remained above 20 mg/dL.

There was no significant difference in values of serum phenylalanine and tyrosine for males and females.

Urinary metabolites were measured in samples obtained from 181 patients (83.8%); phenylalanine and o-HPAA values were elevated above the upper limit of normal (100 mg of phenylalanine per gram of creatinine and 1 mg of o-HPAA per gram of creatinine) in all the infants.

Challenge Data

The protocol called for the challenge to be performed three months after tentative diagnosis and institution of therapy, which occurred at a mean age of 22.4 ± 14.8 days for the group (range, 3 to 92 days of age). Fifteen subjects were not challenged for various reasons (family and/or clinic noncompliance with the protocol, family move to an area without a participating clinic, etc) and were dropped from the study.

Challenge data from 201 patients (93.0%) were available for analysis. However, the limited requirement for blood samples and dietary information during the first years of the study rendered some procedures inadequate for complete evaluation. Additionally, the decision by participants to discontinue the challenge once the phenylal-

†± 4 hours.

anine level exceeded 20 mg/dL led to many abbreviated procedures. Ninety-four procedures (46.7%) continued for 72 hours, while 99 (49.2%) were terminated at various other times (24 hours, 10 patients; 36 hours, 6; 48 hours, 48; 60 hours, 32; more than 72 hours, 3). The remaining eight patients (3.9%) underwent initial challenge with phenylalanine at a mean age of 30.1 ± 18.3 months.

Sixty-seven challenges in which natural protein was administered for 72 hours and serum phenylalanine determinations were obtained at 24, 48, and 72 ± 4 hours are described here. There were 36 boys and 31 girls in this group, ranging in age from 2.2 to 20.7 months at the time of challenge (mean age, 4.8 ± 2.7 months), representing 33.3% of the total challenges performed. Two patients who met the criteria for a complete challenge were dropped from the study at the discretion of the clinic director and are excluded from this analysis.

All infants were physically well at the beginning of the challenge, but two subsequently had fever, which was described as "transient" and "slight" and required no therapy during the procedure. Three infants refused to ingest the prescribed amount of formula; in one of these, the difficulty appeared to be related to mild nasal discharge. Slight irritability was recorded in a single infant. The most common problem was minimal vomiting or spitting up, recorded in ten infants. One infant was gavage fed to ensure adequate intake. In all, 16 infants (5 boys, 11 girls), representing 23.9% of the group, had problems of this nature.

Three types of responses were observed in the serum biochemistry studies (Table 1):

1. Forty-five patients (67.2%) demonstrated a sustained and continuous rise in serum phenylalanine level over the challenge period. In all 45 patients, the highest serum phenylalanine level was recorded at 72 hours (type 1 response). The mean serum phenylalanine level for this group was above 20 mg/dL at 24, 48, and 72 hours. Of the 23 male and 22 female infants in this group, 11 suffered minor physical problems with the procedure: vomiting, 3 boys and 3 girls; refusal of some of the prescribed formula, three girls; slight irritability, one boy; and slight fever, one girl. There was no significant difference between the rate of rise of serum phenylalanine for male and female infants.

2. Seven patients (10.4%) demonstrated a rise of serum phenylalanine level of greater than 20 mg/dL at 24 hours or 48 hours or both after institution of the challenge, but a subsequent decline occurred by 72 hours to less than 20 mg/dL in all, despite continuation of the procedure (type 2 response). Of the four boys and three girls with this response, one boy had transient fever and one girl had minimal vomiting.

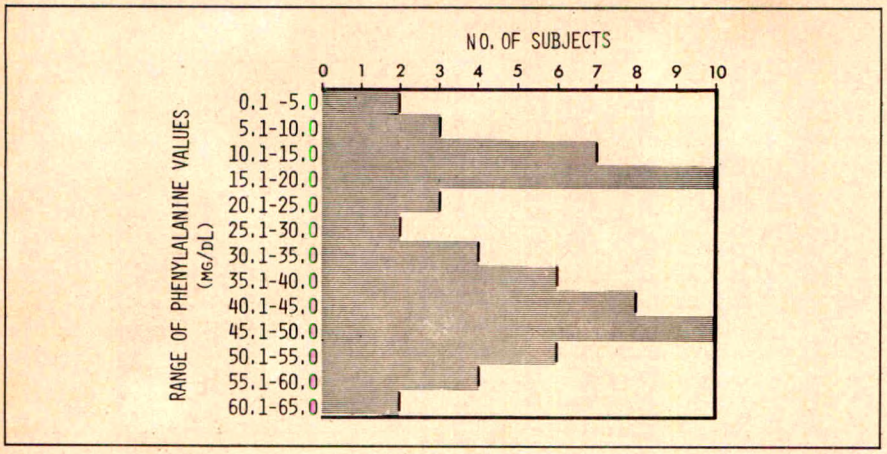
3. Fifteen infants (22.4%) failed to demonstrate a rise in serum phenylalanine level above 20 mg/dL at any point in the challenge procedure (type 3 response). Nine boys and six girls demonstrated this response, of whom three (all female) suffered minimal vomiting during the procedure.

The phenylalanine intake during the challenge was calculated in milligrams per kilogram for each 24-hour period of the procedure (Table 1). There was no statistically significant difference in the amount ingested by patients with types 1, 2, or 3 responses.

Urinary metabolites were measured in samples from 65 of the 67 subjects. Phenylalanine and o-HPAA levels in excess of normal amounts were found in all postchallenge specimens.

Interpretation of Challenge Data

The serum phenylalanine levels in patients with type 2 and 3 responses differed significantly at 0 hours ($P = .02$), 24 hours ($P < .001$), and 48 hours ($P = .02$). At 72 hours, however, there was no significant difference between the two groups. In contrast, the serum phenylalanine determinations of type 1 patients were significantly different at 48 and 72 hours



Frequency distribution of 72-hour phenylalanine levels in 67 patients undergoing natural protein challenge.

*No. of cases.

when compared with those of both types 2 and 3 ($P < .001$ at each time).

When Type 2 and 3 data were analyzed so as to take the difference at 0 hours between the two groups into account, no significant difference was noted. On review of the distribution of the 72-hour phenylalanine levels for all 67 subjects (Figure), two distinct peaks in the 15.1-to-20-mg and 45.1-to-50-mg ranges were noted, supporting the assumption of two distinct populations of subjects. It was therefore agreed that type 2 and 3 responses were characteristic of the individual with variant PKU, and the challenge data of the 22 patients with these responses were pooled, resulting in a pattern considered typical of variant status. While these represent one third of the individuals with complete challenges, it should be emphasized that this incidence is higher than if the whole sample had been available for similar review. Decisions to terminate challenge once serum phenylalanine levels rose above 20 mg/dL tended to reduce the number of procedures lasting 72 hours. In contrast, the slower rise and relatively low levels achieved by the variant individuals led to a greater number of complete procedures.

Review of Variant Status

The initial presentation and course following study discontinuation of these 22 patients with a variant response were reviewed.

Diagnostic Data.—Table 2 lists the mean maximum initial phenylalanine levels for variant and classic PKU patients, together with ranges and SDs. The difference between the 45 classic PKU patients and the 22 variant individuals is highly significant ($P < .001$). There was no significant difference in age and sex between the two groups.

Despite the large difference between the means, it should be noted that the overlap of the values in the two groups limits the usefulness of these data in terms of initial diagnosis.

Course Following Discontinuation From Study.—Decision as to further management of these variant patients differed, reflecting the clinic directors' views of hyperphenylalaninemia, the parent's wishes, and, frequently, the results of further challenges. In general, dietary management was less restricted or discontinued, a formal PKU diet being continued in only one patient. Twelve infants resumed a completely normal diet between 3 and 15 months of age. Two of these, male siblings, were found to suffer from dihydropteridine reductase deficiency and are described elsewhere.[20] The remaining nine patients continued to receive a low phenylalanine diet until 12 to 24 months of age, when the diet was modified by allowing solid foods at will while continuing the low phenylalanine formula. Two of these nine resumed a normal diet at 3 years of age. Mean serum phenylalanine levels in these children once the diet was relaxed or discontinued ranged from 3.1 to 18.4 mg/dL. In no case was it considered necessary to resume a formal phenylalanine-restricted diet on the basis of either persistent serum phenylalanine levels above 20 mg/dL or clinical findings.

The results of follow-up intelligence testing are available for 15 of the 22 variant patients. Their mean IQ on the Stanford-Binet test (1960 norms) was recorded as 102 ± 15, compared with a mean IQ of 103 ± 14 on the

same test for 44 of the 45 patients classified as having classic PKU.

Thus, the variant individuals identified in this study may be characterized as having an initial serum phenylalanine level above 20 mg/dL in early infancy, compatible with the diagnosis of classic PKU. However, 72 hours after institution of a natural protein challenge in later infancy and on resumption of a normal diet, the serum phenylalanine level is persistently recorded as below 20 mg/dL.

Incomplete Challenges

There were 124 patients whose challenges with natural protein were considered incomplete either as to length of procedure or lack of blood sampling at 24, 48, or 72 hours. To determine the status of these patients, the final serum phenylalanine level obtained in each case in which the decision had been made to discontinue the challenge was selected for analysis and comparison with the serial data obtained from those who had complete studies.

One hundred fifteen infants had final serum phenylalanine levels above 20 mg/dL. Four of these were dropped from the study at the discretion of the clinic director and are excluded from the presentation. Table 3 presents the data from the remaining 111 infants, compared with the serial data obtained from the 45 patients with classic PKU described previously. The mean serum phenylalanine value recorded prior to 72 hours substantiates the reasoning behind early discontinuation of the challenge in these cases, particularly at 24 hours. There is no significant difference between these groups, and the diagnosis of classic PKU in these 111 patients appears to be clear.

There were nine patients whose final serum phenylalanine level was reported to be below 20 mg/dL. One, whose phenylalanine intake during the challenge averaged only 108 mg/kg/day, underwent a later procedure with *l*-phenylalanine (average intake, 187 mg/kg/day) and achieved a 72-hour serum level of above 20 mg/dL. The remaining eight patients were given less restricted or normal diets; all but one maintained phenylalanine levels below 20 mg/dL. This exception, a patient for whom dietary information during the challenge was inadequate, had a phenylalanine level above 30 mg/dL and was considered to have classic PKU. These two patients were continued in the study as subjects. Table 4 demonstrates the final serum phenylalanine levels of the remaining seven patients compared with the serial levels obtained in the 22 variant patients described previously. There is no statistically significant difference between these groups, and these seven responses are considered compatible with the variant state.

Table 4.—Final Serum Phenylalanine Levels < 20 mg/dL in Subjects With Incomplete and Complete Challenges

Time, hr	Mean Serum Phenylalanine, mg/dL: Complete Challenges (Variant Response) (N = 22)	Mean Serum Phenylalanine, mg/dL: Incomplete Challenges (N = 7)
24 ± 4	15.7 ± 5.3 (22*)	. . .
48 ± 4	15.6 ± 4.9 (22)	. . .
61 ± 4.6	. . .	16.0 ± 2.5 (2)
72 ± 4	13.5 ± 5.2 (22)	15.3 ± 3.3 (4)
> 76	. . .	14.1 (1)

*No. of cases.

Table 5.—Classification of 195 Study Patients Into Classic and Variant Phenylketonuria (PKU)*

Method of Classification	Classic PKU	Variant PKU
Natural protein challenge		
Complete	45	22
Incomplete	111	7
Phenylalanine (L-phenylalanine) challenge	8	0
Return to normal diet (temporary	1	0
Second phenylalanine challenge	1	0
Total	**166** (85.1%)	**29** (14.9%)

*Of 216 patients initially admitted to the study, 201 underwent challenge. Six were dropped from the study by the clinic director.

L-Phenylalanine Challenges

The final serum phenylalanine levels in the eight patients undergoing phenylalanine challenge were all above 20 mg/dL (Table 3). Although interpretation of phenylalanine challenges may be difficult,[21] the pattern seen in these patients is compatible with classic PKU.

Classification of the Study Subjects

Table 5 summarizes the classification of the study patients' diagnoses into classic and variant PKU. It can be seen that 29 (14.9%) of the 195 infants were categorized as having variant PKU, all of whom were dropped from the study. The remaining 166 patients (85.1%) appear to fulfill criteria for classic PKU, and the study participants agreed they should continue as subjects.

COMMENT

In the early years of PKU screening, it was generally believed that any serum phenylalanine level above normal was synonymous with actual or potential mental retardation, regardless of the degree of elevation. Thus, some early case reports describe patients with modest elevations of 6 to 12 mg/dL diagnosed as having PKU and treated. Other, usually older children were described as suffering from atypical PKU in view of normal intellectual development without treatment despite serum phenylalanine levels in that range. When newborn screening programs unexpectedly detected a greater number of infants with elevated serum phenylalanine levels than would have been predicted on the basis of the known incidence of PKU, it became clear that a variant of PKU existed that had a vastly different prognosis for intellectual development.

At the time the Collaborative Study Protocol was being developed in 1966 and 1967, knowledge of the variant state was limited but adequate enough to assure the adoption not only of stringent criteria for entry into the study but also of a later phenylalanine challenge to confirm the diagnosis. The value of the challenge is clear: the diagnosis in almost 15% of infants admitted to the study proved to be incompatible with classic PKU. While this incidence is lower than anticipated on the basis of recent data,[8] it can largely be accounted for by the study admission requirement that each subject have serum phenylalanine levels of 20 mg/dL or greater, thus leading to exclusion of the larger population of hyperphenylalaninemic patients with lower levels. A minor factor affecting the incidence may be the use of the 20-mg/dL level as the challenge criterion. This may be too stringent and a few variant subjects may remain undetected in the study population.

Few would question the institution of therapy for patients with a mean serum phenylalanine level of 30 mg/dL early in life; however, continuation of treatment on the basis of the initial data alone must be considered questionable for many. Although no infant in this study had serious problems related to a restricted diet, continuation of such restriction has potential hazards. The emotional cost to the family responsible for maintaining the PKU diet is considerable, and the cost of providing low phenylalanine formula over several years cannot be ignored. Genetic counseling given initially to these families dealt primarily with classic PKU; although variant hyperphenylalaninemia is also inherited as an autosomal recessive characteristic, the prognosis for subsequent offspring differs considerably from that for those with classic PKU.

In practice, the variant state may be suspected by a more rapid decline in serum phenylalanine levels following introduction of treatment than is usually seen in classic PKU. Information on this point is episodic and is influenced by the various methods of introducing treatment in different clinics.[22] Additionally, variant patients may show a greater tolerance for phenylalanine than that seen in the classic individual, which is most marked in later infancy and childhood. Individual variations between infants in requirements for phenylalanine may be great,[17] but this difference may not be evident in the first few weeks of life. The use of a standard challenge appears to be a reliable method to determine variant status and is recommended for use in all infants diagnosed as suffering from PKU.

The milk challenge described here proved easy to perform in many different clinics both on an inpatient and outpatient basis. The morbidity was minor and the gains to the patient were unquestionable. Had this procedure not been performed, not only would 29 children have been continued on rigorous dietary restriction without proved benefit, but the study population would have been contaminated, with approximately one of six of its patients likely to do well intellectually without treatment.

The Project Staff of the Collaborative Study of Children Treated for Phenylketonuria include the following: Richard Koch, MD, *Medical Director*, 1967-1975, 1976-present; George Donnell, MD, *Medical Director*, 1975-1976; Malcolm L. Williamson, PhD, *Project Co-director;* James C. Dobson, PhD, *Project Co-director*, 1967-1977; Eva Gross Friedman, *Project Coordinator*. The following clinics participated in this study: Oregon State Board of Health, Portland; University of Wisconsin Medical Center, Madison; Children's Hospital of Los Angeles; Children's Memorial Hospital, Chicago; Children's Medical Center, Tulsa, Okla; Milwaukee Children's Hospital; University of Colorado, Denver; University of Washington, Seattle; Loyola University School of Medicine, Maywood, Ill; Children's Hospital and Health Center, San Diego; University of Illinois Hospital, Chicago; Chicago Medical School; University of Texas, Medical School Branch, Galveston; State University of New York, Syracuse; University of Miami (Fla); University of Iowa, Iowa City; University of Maryland School of Medicine, Baltimore; State Department of Health, Baltimore; Johns Hopkins Hospital, Baltimore; Children's Hospital, Buffalo; and University of Nebraska, Omaha. Samuel Bessman, MD, and Kenneth N. F. Shaw, PhD, served as Laboratory Directors.

This investigation was supported in part by grant MCT-000466 from the Bureau of Community Health Services, Health Services Administration.

The String Test for Gastroesophageal Reflux

William M. Liebman, MD, Philip Rosenthal, MD

• The sensitivity of the string test for detection of gastroesophageal reflux was assessed in 15 infants and children, 5 months to 11 years of age (mean, 2.8 years), with vomiting, regurgitation, or lower respiratory tract symptoms, and compared with the barium esophagram, esophageal manometry, and the acid reflux test (pH probe). Barium esophagram showed reflux in 4/15 patients, pH probe in 7/15, and string test in 6/15. The string test is a simple, rapid, safe, and efficient screening method for patients with suspected gastroesophageal reflux.
(*Am J Dis Child* 134:775-776, 1980)

Vomiting is one of the most frequent problems confronting the pediatrician. The predominant mechanism implicated in most cases has been gastroesophageal reflux (GER), vomiting being its most frequent symptom.[1-4] The present study was undertaken to evaluate the sensitivity of the string test (Gastro-Test), a simple, accurate technique, in detection of GER in comparison to the barium esophagram, esophageal manometry, and acid reflux test (pH probe).[5]

PATIENTS AND METHODS

Fifteen infants and children (5 months to 11 years, mean, 2.8 years; six males and nine females) with recurrent vomiting, regurgitation, or recurrent lower respiratory tract symptoms were evaluated for GER. The string test, esophageal manometry, and the acid reflux test were performed on the same day. Sedation (meperidine hydrochloride [Demerol] and promethazine hydrochloride [Phenergan], 1 mg/kg, parenterally) was used in patients younger than 5 years of age. All patients were fasted for at least six to eight hours. The string test was also performed in 45 infants and children (5 months to 15 years; 24 males and 21 females) with chronic diarrhea of undetermined cause. Informed consent was obtained in all patients.

Measurement of lower esophageal sphincter pressure was performed as described by Arndorfer.[6] The acid reflux test was accomplished by use of the microcecar combination electrode as described by Euler et al.[1,2] Reflux was established when a pH of 3 or less on two occasions (15 s or more per episode) was recorded in the supine, prone, right, or left lateral positions. Spontaneous and induced reflux were evaluated before and after introduction of 0.1N hydrochloric acid into the stomach (300 mL/1.73 sq m body surface area).[1-4] The acid was aspirated at the end of the procedure.

The string test (Gastro-Test used for those older than 2 years of age and Entero-Test-Pediatric (for those younger than 2 years) was performed on all patients. After a six- to eight-hour fast, the patient swallowed the capsule with water, or the capsule was placed in the posterior pharynx and then swallowed. The free end of the string was taped to the cheek and normal activity was resumed. After 15 minutes, the string was pulled out and examined. The distance (centimeters) from the incisors to any area with color indicative of a pH of less than 3.0 was measured. Approximate anatomic correlation was recorded.[5]

Barium esophagram was performed on all patients with suspected GER. The presence or absence of reflux was assessed, as was the level of reflux.

RESULTS

Seven patients (47%) had positive acid reflux tests and six (38%) positive string tests. Acid reflux was confirmed at both a 15- and 20-cm distance from the incisors in the six patients with positive string tests.

Lower esophageal sphincter (LES) pressures were measured in all patients without incident. Lower esophageal sphincter pressure (mean ± SD) was significantly less in the seven patients with reflux in comparison with eight without reflux (14.1 ± 1.11 mm Hg vs 19.2 ± 1.11 mm Hg, respectively, $P < .025$). Barium esophagram showed reflux in four of 15 patients. Of eight patients

without acid reflux, all had normal roentgenographic examinations. Of seven patients with acid reflux by pH probe and six by string test, four had reflux demonstrated by barium examination. The string test was negative in all of the 45 patients with diarrhea.

COMMENT

Recent studies have confirmed the sensitivity of the acid reflux test in establishing GER.[1,2,4,7] Furthermore, the acid reflux test has been found to be superior to the barium esophagram in diagnosing GER.[1,4] Our percentage of positive barium examinations for GER were comparable to that of Christie,[4] while being considerably higher than that reported by Euler and Ament,[1,2] and lower than some roentgenographic investigators have reported.[3,8]

More recently, a promising technique for demonstrating and quantitating GER has been developed that involves ingestion of technetium TC 99m sulfur colloid and subsequent scanning of the gastroesophageal area.[9] This scintiscan procedure does expose the patient to a small amount of radiation and requires special equipment. Correlation with the pH probe test has been good.[9,10] Another new technique, for detection of GER involves the use of methylene blue.[11,12] This test does involve the use of a nasogastric tube for insertion of methylene blue in 0.1N hydrochloric acid into the stomach, as well as placement of a polyvinyl tube with multiple openings and cotton thread inside to detect staining with methylene blue. This tube was kept in place in the lower esophagus for as long as two hours in the initial studies.[11,12] The correlation with results of the barium examination and with the pH probe test has been good.[11,12] The present study has demonstrated the string test to be rapid, accurate, inexpensive, and safe in all age groups. The correlation with the acid reflux test is excellent, and in addition, the capability of approximate localization of reflux during the same test period without need for the use or relocation of any instrument, any radiation exposure, or potential complications makes it particularly attractive as a screening test for patients with suspected GER.

Barbara Jarvis provided secretarial assistance. The Hedero Corp provided the Gastro-Test and Enterotest-Pediatric Capsules for this study.

Rotavirus Gastroenteritis in the Washington, DC, Area

Incidence of Cases Resulting in Admission to the Hospital

William J. Rodriguez, MD, PhD; Hyun Wha Kim, MD; Carl D. Brandt, PhD; Bernard Bise, PhD; Albert Z. Kapikian, MD; Robert M. Chanock, MD; George Curlin, MD; Robert H. Parrott, MD

• The incidence of rotavirus gastroenteritis in infants and children that required admission to the hospital was estimated for a defined population of approximately 105,000 individuals, including 29,000 children aged 15 years or younger whose primary health care was provided by Group Health Association, Inc, a health maintenance organization in the Washington, DC, area. From January 1977 through March 1979, almost all infants and children in this age group who required hospitalization for gastroenteritis were studied for evidence of infection with human rotavirus (HRV) and other agents. On the average, one in 272 (3.7/1,000) infants less than 12 months old and one in 451 (2.2/1,000) children aged 13 through 24 months were hospitalized for HRV disease each winter. The incidence of rotavirus gastroenteritis requiring hospitalization declined precipitously in children after the second birthday and such illness was not detected in children aged 5 years or older. The role of other agents in acute gastroenteritis requiring hospitalization was minimal, compared with that of rotavirus.

(*Am J Dis Child* 134:777-779, 1980)

Human rotavirus (HRV) has proved to be the major etiologic agent of serious acute gastroenteritis in infants and children less than 2 years old wherever this disease has been studied throughout the world.[1-4] The importance of HRV as a cause of such gastroenteritis has been ascertained primarily in studies of infants and children hospitalized with this disease.[1-5] However, in such studies, incidence rates of hospitalization caused by HRV infection could not be derived since it was not possible to define precisely the population from which the hospitalized patients came. In an attempt to obtain such rates, we undertook a study of the incidence of pediatric HRV gastroenteritis in a well-defined pediatric population whose medical care is provided by Group Health Association, Inc (GHA), a health maintenance organization in the Washington, DC, metropolitan area. Almost all hospitalizations of children enrolled in the GHA occurred at our hospital.

Reprint requests to Microbiology Section, Research Foundation Children's Hospital National Medical Center, 111 Michigan Ave NW, Washington, DC 20010 (Dr Rodriguez).

PATIENTS AND METHODS

The GHA serves individuals at varied income levels in government and private industry in the Washington, DC, area and utilizes Children's Hospital National Medical Center (CHNMC) as its hospital for pediatric admissions. The average family enrolled in GHA has 3.8 members, and a demographic profile of these individuals closely resembles that of the total population of the District of Columbia (unpublished information, Group Health Association, Inc, Washington, DC, 1978). The total population served by the GHA numbers approximately 105,000 and about 28% of these are younger than 15 years old. Approximately one third of the families reside in areas closely adjacent to the

†Rotavirus was detected in the stools of all patients except one (in the under-12-month age group in 1978) who had a serologic response to rotavirus.

CHNMC, while the remainder are located throughout the Washington metropolitan area. Fifty-four percent of the GHA population is black. The majority of families has an annual income between $10,000 and $25,000.

Patients with complaints of gastroenteritis were seen by the pediatricians of the GHA who provided the outpatient care. Outpatient visits to GHA clinics for diarrhea were recorded on computer records and the information was made available to us, but these illnesses were not studied for viral etiology. Etiologic studies were performed for infants and children enrolled in the GHA who were admitted to the CHNMC for acute gastroenteritis. Criteria for hospitalization were not specifically defined, and the decision to admit was left to the individual pediatrician.

After informed consent had been obtained, stool specimens were collected for detection of viral and bacterial enteric pathogens. Acute and convalescent phase sera were also collected and tested by complement fixation technique for HRV antibody.[6,7] Stool specimens were tested as 2% filtrates or in 2% to 20% suspensions for HRV by electron microscopy (EM), immune electron microscopy (IEM), and rotavirus group enzyme-linked immunosorbent assay.[8-11] Routine bacteriologic testing was performed on stool specimens, in addition to tests for *Campylobacter* sp,[12] *Yersinia* sp,[13] and *Vibrio parahemolyticus*.[14] Assays were also made for heat-labile and heat-stable coliform toxins.[15,16]

RESULTS

Between January 1977 and March 1979, during which time there were three periods of rotavirus prevalence in the community, approximately 29,000 individuals 15 years old or younger were enrolled in the GHA population (Table). The population at risk remained relatively stable during the 27-month period in its total and subgroup profile.

Although the computer-based data on the incidence of gastroenteritis in the GHA outpatient facilities are complete only for calendar years 1977 and 1978, etiologic studies on hospitalized patients are complete through March 1979. Therefore, the estimates for incidence of clinical gastroenteritis are based on a 24-month period, and the estimates for the incidence of hospitalization for HRV infection are based on a 27-month period.

During 1977 and 1978, 1,848 individuals 15 years old or younger were seen in GHA clinics for gastrointestinal illness; the majority of such illnesses occurred in individuals younger than 5 years old. Children 2 years old and younger had 1,011 gastrointestinal illnesses that necessitated a visit to the clinic; this period of observation represented 4,628 person-years. Thus, one of every five individuals at risk in the 24-month-old and younger age group was seen in the clinic for diarrheal disease during 1977 and 1978. During the same 24-month period, 23 GHA patients were hospitalized for gastroenteritis; 19 of them were 2 years old or younger. In this two-year period, approximately one in every 157 infants younger than 1 year old and one in every 485 children in the 1- to 2-year-old age group was hospitalized for gastroenteritis.

From January 1977 through March 1979 (27 months), specimens from 30 of 31 hospitalized GHA patients who were 24 months old and younger were studied microbiologically. Nineteen (63%) of these 30 patients had rotavirus detected in their stools, and one who did not shed rotavirus had a serologic response to rotavirus. The majority of these rotavirus illnesses (12 of 23) requiring hospitalization occurred in individuals younger than 1 year old. Of individuals at risk, one in 272 younger than 1 year old was hospitalized for rotavirus disease (3.7 hospitalized for rotavirus disease per 1,000 at risk per year); the comparable rate for individuals in the 1- to 2-year-old age group was one in 451 (2.2 hospitalized for rotavirus disease per 1,000 at risk per year). Pediatric patients whose specimens were positive for rotavirus and who required hospitalization included 12 black and 11 white patients, a distribution paralleling that of the GHA population. Seven of the white patients and nine of the black patients were male. There were 2.3 times more males than females hospitalized for rotavirus disease. In addition to these younger infants and children, all three children in the 26 to 60-month-old age group and none of four older children hospitalized for gastroenteritis had rotavirus infection.

When hospital admission patterns

for gastroenteritis of any etiology were examined by month, 28 of the 37 (76%) admissions in the study population occurred during January, February, and March.

Other Enteric Pathogens

The specimen from one patient in the 1- to 12-month-old age group yielded a coliform that produced heat-labile enterotoxin. The specimen from one patient 103 months old yielded *Shigella D*. Two patients shed salmonellae, one was in the 1- to 2-year-old age group and the other in the 6- to 15-year-old age group. *Yersinia enterocolitica* was recovered from the stool of one patient, which also yielded rotavirus.

Hospitalization Charges

In 1978 and 1979, the length of hospitalization for 15 of 18 patients with rotavirus disease and from whose records fiscal data were available ranged from one to 13 days, with a mean of 3.8 days. The average charges for hospitalization were $1,530 per patient (minimum, $421; maximum, $4,030).

COMMENT

We have previously reported detection of rotavirus infection in approximately one half of all pediatric patients hospitalized with gastroenteritis.[1] Due to the seasonality of the virus in our area, this percentage increased to 61% during the winter months.[5] In the present study, rotavirus infection was detected in 62% of the 37 pediatric admissions for gastroenteritis studied microbiologically from the population served by GHA in a 27-month period that included three periods when rotavirus infection was prevalent. With the exception of one patient who had dual infection with *Yersinia* organisms and rotavirus, other etiologic agents occurred independently of rotavirus. However, the role of other agents in acute gastroenteritis was minimal; in addition to the *Yersinia* infection cited above, only one patient had a coliform that produced heat-labile enterotoxin, one shed a *Shigella D*, and two patients shed *Salmonella*.

The incidence of hospital admission for rotavirus gastroenteritis in the first two years of life was 2.9 per 1,000 population per epidemic interval. The importance of this virus in gastroenteritis severe enough to necessitate hospital admission decreased precipitously after 2 years of age. From the GHA population, we observed only three patients older than 24 months who had rotavirus in their stools or who demonstrated a significant seroresponse to rotavirus. When examined by calendar month, the proportion of inpatients with gastroenteritis who shed rotavirus was essentially that observed previously during our cross-sectional studies.[1-4] In a previous report, we indicated that patients with gastroenteritis associated with rotavirus were hospitalized for a mean of four days (range, two to 14 days).[5] Thus, the mean (3.8 days) and range (one to 13 days) of hospitalization observed for the GHA patients was comparable to that of the total population served by the CHNMC. This is not surprising, since the GHA population represented a cross-section of the Washington metropolitan area population, and the data derived can thus be applied generally to our urban area.

If the incidence figures are applicable nationwide, the cost of hospitalization for rotavirus gastroenteritis, extrapolated for the United States, would be approximately $27 million per year for the 6,600,000 children less than 24 months old. This estimate may be somewhat high, since it is based on a specialty hospital in the Washington, DC, area. However, the cost of nonhospitalized rotavirus disease (which we are investigating) undoubtedly will extend the monetary impact of rotavirus disease considerably.

Data derived from studying hospitalized patients from this GHA population suggest that at least 50% of admissions for dehydrating gastrointestinal illness are associated with rotavirus. This information, along with outpatient cost data, when it becomes available, should aid in establishing priorities for the need to prevent serious pediatric rotavirus gastroenteritis within the framework of national health care policy.

This research was supported in part by National Institute of Allergy and Infectious Diseases contract 1-A1 72535.

Group Health Association, Inc, and Geroge Joseph, MD, cooperated in this study.

You can help the ADD* child with Cylert
(pemoline)

Day-long behavior therapy without dosing problems at school

Impressive all-day control.

Cylert works extremely well, given an adequate period of trial. Single daily doses are as effective for behavior control as multiple doses of methylphenidate or amphetamines. Blood levels are well sustained, without necessity for multidose administration.

No troublesome midday dose.

Cylert avoids problems of taking a drug at school. No involvement of school personnel. No peer teasing about noon-time dosing. The parents manage all medication, and the child carries no drugs. (And note that Cylert is Schedule IV, not II.)

Cylert® C IV

(pemoline)

18.75, 37.5, 75 mg tablets; 37.5 mg chewables

Just once a day. At home.

*ADD: Attention Deficit Disorder (formerly called MBD, Minimal Brain Dysfunction), or the Hyperkinetic Syndrome. Please see next page for Brief Summary.

ABBOTT

Cylert® (pemoline)

DESCRIPTION: CYLERT (pemoline) is a central nervous system stimulant. Pemoline is structurally dissimilar to the amphetamines and methylphenidate.

It is an oxazolidine compound and is chemically identified as 2-amino-5-phenyl-2-oxazolin-4-one.

Pemoline is a white, tasteless, odorless powder, relatively insoluble (less than 1 mg./ml.) in water, chloroform, ether, acetone, and benzene; its solubility in 95% ethyl alcohol is 2.2 mg./ml.

CYLERT (pemoline) is supplied as tablets for oral administration.

CLINICAL PHARMACOLOGY: CYLERT (pemoline) has a pharmacological activity similar to that of other known central nervous system stimulants; however, it has minimal sympathomimetic effects. Although studies indicate that pemoline may act in animals through dopaminergic mechanisms, the exact mechanism and site of action of the drug in man is not known.

There is neither specific evidence which clearly establishes the mechanism whereby CYLERT produces its mental and behavioral effects in children, nor conclusive evidence regarding how these effects relate to the condition of the central nervous system.

The serum half-life of pemoline is approximately 12 hours. Peak serum levels of the drug occur within 2 to 4 hours after ingestion of a single dose. Multiple dose studies in adults at several dose levels indicate that steady state is reached in approximately 2 to 3 days.

Metabolites of pemoline include pemoline conjugate, pemoline dione, mandelic acid, and unidentified polar compounds. CYLERT is excreted primarily by the kidneys; approximately 75% of an oral dose is recovered in the urine within 24 hours. Approximately 43% of pemoline is excreted unchanged.

CYLERT (pemoline) has a gradual onset of action. Using the recommended schedule of dosage titration, significant clinical benefit may not be evident until the third or fourth week of drug administration.

INDICATIONS: CYLERT is indicated as an integral part of a total treatment program which typically includes other remedial measures (psychological, educational, social) for a stabilizing effect in children with a behavioral syndrome characterized by the following group of developmentally inappropriate symptoms: moderate to severe distractibility, short attention span, hyperactivity, emotional lability, and impulsivity. The diagnosis of this syndrome should not be made with finality when these symptoms are only of comparatively recent origin. Nonlocalizing (soft) neurological signs, learning disability, and abnormal EEG may or may not be present, and a diagnosis of central nervous system dysfunction may or may not be warranted.

Attention Deficit Disorder and Hyperkinetic Syndrome are among the terms being used to describe the above signs and symptoms. In the past, a variety of terms has been associated with these signs and symptoms, including: Minimal Brain Dysfunction, Hyperkinetic Reaction of Childhood, Hyperkinetic Syndrome, Hyperactive Child Syndrome, Minimal Brain Damage, Minimal Cerebral Dysfunction, and Minor Cerebral Dysfunction.

CONTRAINDICATIONS: CYLERT (pemoline) is contraindicated in patients with known hypersensitivity or idiosyncrasy to the drug. (See ADVERSE REACTIONS.)

WARNINGS: CYLERT is not recommended for children less than 6 years of age since its safety and efficacy in this age group have not been established.

Clinical experience suggests that in psychotic children, administration of CYLERT may exacerbate symptoms of behavior disturbance and thought disorder.

Data are inadequate to determine whether chronic administration of CYLERT may be associated with growth inhibition; therefore, growth should be monitored during treatment.

PRECAUTIONS: Drug treatment is not indicated in all cases of the behavioral syndrome characterized by moderate to severe distractibility, short attention span, hyperactivity, emotional lability and impulsivity. It should be considered only in light of the complete history and evaluation of the child. The decision to prescribe CYLERT should depend on the physician's assessment of the chronicity and severity of the child's symptoms and their appropriateness for his/her age. Prescription should not depend solely on the presence of one or more of the behavioral characteristics.

When these symptoms are associated with acute stress reactions, treatment with CYLERT is usually not indicated.

Long-term effects of CYLERT in children have not been well established.

Liver function tests should be performed prior to and periodically during therapy with CYLERT. The drug should be discontinued if abnormalities are revealed and confirmed by follow-up tests. (See ADVERSE REACTIONS regarding reports of abnormal liver function tests and jaundice.)

CYLERT should be administered with caution to patients with significantly impaired hepatic or renal function.

The interaction of CYLERT with other drugs has not been studied in humans. Patients who are receiving CYLERT concurrently with other drugs, especially drugs with CNS activity, should be monitored carefully.

CYLERT failed to demonstrate a potential for self-administration in primates. However, the pharmacologic similarity of pemoline to other psychostimulants with known dependence liability suggests that psychological and/or physical dependence might also occur with CYLERT. There have been isolated reports of transient psychotic symptoms occurring in adults following the long-term misuse of excessive oral doses of pemoline. CYLERT should be given with caution to emotionally unstable patients who may increase the dosage on their own initiative.

Usage during Pregnancy and Lactation: The safety of CYLERT (pemoline) for use during pregnancy and lactation has not been established.

Studies in rats have shown an increased incidence of stillbirths and cannibalization when pemoline was administered at a dose of 37.5 mg./kg./day. Postnatal survival of offspring was reduced at doses of 18.75 and 37.5 mg./kg./day.

ADVERSE REACTIONS: Insomnia is the most frequently reported side effect of CYLERT; it usually occurs early in therapy, prior to an optimum therapeutic response. In the majority of cases it is transient in nature or responds to a reduction in dosage.

Anorexia with weight loss may occur during the first weeks of therapy. In the majority of cases it is transient in nature; weight gain usually resumes within three to six months.

Stomach ache, skin rashes, increased irritability, mild depression, nausea, dizziness, headache, drowsiness, and hallucinations have been reported.

Elevations of SGOT, SGPT, and serum LDH have occurred in patients taking CYLERT, usually after several months of therapy. These effects appear to be reversible upon withdrawal of the drug, and are thought to be manifestations of a delayed hypersensitivity reaction. There have also been a few reports of jaundice occurring in patients taking CYLERT; a causal relationship between the drug and this clinical finding has not been established.

The following CNS effects have been reported with the use of CYLERT: dyskinetic movements of the tongue, lips, face and extremities, nystagmus and nystagmoid eye movements, and convulsive seizures. A definite causal relationship between CYLERT and these reactions has not been established.

Mild adverse reactions appearing early during the course of treatment with CYLERT often remit with continuing therapy. If adverse reactions are of a significant or protracted nature, dosage should be reduced or the drug discontinued.

OVERDOSAGE: Signs and symptoms of acute CYLERT overdosage may include agitation, restlessness, hallucinations, dyskinetic movements and tachycardia. The treatment for an acute overdosage of pemoline is essentially the same as that for an overdosage of any CNS stimulant. Management is primarily symptomatic and may include induction of emesis or gastric lavage, sedation, and other appropriate supportive measures.

Results of studies in dogs indicate that extracorporeal hemodialysis may be useful in the management of CYLERT overdosage; forced diuresis and peritoneal dialysis appear to be of little value.

DOSAGE AND ADMINISTRATION: CYLERT (pemoline) is administered as a single oral dose each morning. The recommended starting dose is 37.5 mg./day. This daily dose should be gradually increased by 18.75 mg. at one week intervals until the desired clinical response is obtained. The effective daily dose for most patients will range from 56.25 to 75 mg. The maximum recommended daily dose of pemoline is 112.5 mg.

Clinical improvement with CYLERT is gradual. Using the recommended schedule of dosage titration, significant benefit may not be evident until the third or fourth week of drug administration.

Where possible, drug administration should be interrupted occasionally to determine if there is a recurrence of behavioral symptoms sufficient to require continued therapy.

Denouement and Discussion

Marcus Gunn Phenomenon

Fig 1.—Mouth closed and relaxed and eyelid is ptotic.

Fig 2.—Mouth opened and right eyelid is raised.

Fig 3.—Jaw is relaxed during sucking.

Fig 4.—Infant is sucking and eyelid is raised.

Manifestations

Marcus Gunn phenomenon consists of unilateral ptosis at rest with elevation of the eyelid when the mouth is open. This condition is classified under the general heading of "synkinetic ptosis," and the most common type is trigemino-oculomotor synkinesis, or the jaw-winking phenomenon. It is most noticeable during infancy, at which time rapid up and down movements of the eyelid are apparent when the infant is nursing. If the jaw is deviated to the affected side, the ptosis increases but if it is deviated to the unaffected side or if the jaw is projected forward, elevation of the eyelid occurs. It is usually present on the left side and is almost always unilateral. Although there are various theories concerning the etiology of this phenomenon, most believe that during embryogenesis the fifth cranial nerve (trigeminal) fibers were misdirected into the third cranial nerve (oculomotor). As a result of this, when the mouth is open, or sucking takes place, nerve impulses are sent to the external pterygoid muscle which activates the levator palpebral superioris muscles on the same side via the third nerve, causing the eyelid to elevate.

Genetics

It is usually sporadic, although it has been reported inherited in an irregular autosomal dominant manner.

Treatment

Some of the patients have spontaneous improvement with age. Surgical treatment consists of bilateral levator tenotomy and suspension of both eyelids from the brows with a fascia lata sling. In more severe cases the cosmetic results of the surgical resection are not cosmetically better than the original condition.

Review

Hypernatremic Dehydration of Infancy

An Epidemiologic Review

Nigel Paneth, MD, MPH

Hypernatremic dehydration (HD) is dehydration associated with an elevated serum sodium concentration that is generally defined as a level of 150 mEq/L or higher. Hypernatremia is seen in a variety of clinical states in infancy, but this article is concerned with its occurrence in the clinical setting of diarrheal dehydration in otherwise healthy infants. Such a focus is a practical one, as this is the setting for well over 90% of the cases of HD in infants younger than 2 years of age. Diabetes insipidus, renal disease, mental deficiency, and a number of other conditions may predispose to HD, but although they may help elucidate pathophysiologic findings, they are relatively unimportant contributors to the overall incidence of the disorder.

CLINICAL FEATURES

The clinical importance of HD stems from its noticeable distinction from nonhypernatremic dehydration (NHD) as a clinical problem. Almost all clinical reports comment on its relatively high mortality (Table 1). Infants with HD usually have a very different clinical appearance from infants with NHD. They have fewer of the familiar signs of dehydration, such as weak pulses and poor capillary perfusion, and more signs of CNS dysfunction—irritability, lethargy or even coma, and convulsions. A number of observers have noted a peculiar "doughy" feeling to their skin. These differences have been explained by the fact that sodium is essentially an extracellular ion and so tends to draw water into the interstitial and intravascular space, thus maintaining intravascular volume at the expense of cellular desiccation, including desiccation of the cells of the brain and the skin. As the brain is enclosed within a fixed size container, its shrinkage causes vascular damage, capillary and venous congestion, subarachnoid and parenchymal hemorrhages, and thrombosis of venous sinuses. These abnormalities and occasionally subdural hematomas as well have been found frequently in autopsied cases.[1,9-11] This pathophysiologic sequence has been well documented in animals in which the disorder has been experimentally reproduced.[12,13] Parallel to these findings are the elevated CSF protein and xanthochromia commonly found in HD.[1,14,15] The risk of CNS signs increases with the serum sodium concentration and has been reported to be as high as 70% in infants with serum sodium concentrations greater than 158 mEq/L.[7] It is apparent that the rate of development of hypernatremia plays an important role in the degree of CNS dysfunction.

Treatment of HD is difficult as the clinician must tread a fine line between correcting the hypernatremic state and inducing further CNS signs, especially convulsions, by overly rapid water administration. Convulsions are in fact common during therapy,[3,5,16] and autopsied cases that have received intravenous therapy have often shown cerebral edema in the presence of severe dehydration.[5,14,16]

Even if the infant with HD survives both disease and therapy, it is by no means certain that he or she will be left without a residual handicap. Infants with severe brain damage after HD have been described by several authors.[3,11,17,18] Two systematic attempts to trace and examine survivors have been reported in the literature.[5,18] The rates of persistent neurologic abnormality found have been 11% and 15%, consisting of intellectual deficits, seizure disorders, and spastic plegias. It should be noted that in neither study were patients with NHD followed up, nor could the authors give assurance that their patients with HD were free of brain damage prior to their illness. In a common disorder, even a small eleva-

Reprint requests to G. H. Sergievsky Center, 630 W 168th St, New York, NY 10032 (Dr Paneth).

tion in the risk of neurologic or intellectual deficit cannot be ignored, and the claim has been made that, "1,000 children of school age may have an educational or social handicap attributable to hypernatremia" in the United Kingdom.[19]

The high mortality and brain-damaging effects of HD clearly make it a disease worth preventing. But this assertion raises important questions as to the nature of HD. To what extent is it a separate entity from NHD? Is it simply one tail of the distribution of diarrheal dehydration, that associated with a high serum sodium concentration? Is it perhaps a particularly severe form of dehydration, the expected outcome for all infantile dehydration if allowed to progress long enough? Is it a disease caused by a separate agent? Is it the response of certain hosts to infection with the same causative agent associated with NHD? Before attempting to frame an epidemiologic answer to these questions, it will be useful to review the pathogenetic mechanisms likely to be operative in the production of HD.

PATHOGENESIS

Infants, because of certain physiologic characteristics, are predisposed to becoming dehydrated. They have a much larger surface area in relation to height or weight than do adults, and consequently have relatively larger evaporative water losses. Although it is not clear exactly at what age infants are able to fully concentrate urine, some normal infants are unable to concentrate beyond 700 mOsm/L in the early months of life.[20-22] Thus, infants would be expected to require larger amounts of water to excrete a given renal solute load. These two factors are probably the primary reason for the fact that a 4-kg infant has a daily water turnover 20% that of a 70-kg adult, despite weighing only 6% as much.[23] Thus, limitation of access to fluids or excessive losses of fluid of any sort would be expected to lead to dehydration much more rapidly in an infant than in an adult. It should be noted that these factors all deal with the infant's relation to water, so that one might ask why hypernatremia does not occur in all dehydrated infants. Nonetheless, in all parts of the world, the largest proportion of dehydrated infants have serum sodium levels within the normal range. Presumably, enteric losses of salt and water are kept in balance by the combination of oral intake and physiologic adjustments.

Table 2 gives some of the factors that might predispose an infant to hypernatremia, given diarrheal dehydration. Included in Table 2 are the known disease states that predispose to HD and their mechanism of action. Some of these mechanisms are age dependent in a roughly linear fashion. For example, the infant's relative lack of renal concentrating ability is more pronounced in the newborn period and especially so in premature infants. It is also apparent that these mechanisms may very well act in concert. A very young infant will not be able to handle the dietary renal solute load appropriate for an older infant, and particularly so if he or she is febrile.

It can be seen that the determinants of hypernatremia in a dehydrated infant are quite well understood. The distribution of these determinants is, however, poorly documented, and so the relative importance of any one of these mechanisms in producing HD in the population of infants cannot be weighed against any other.

EPIDEMIOLOGY OF NONSPECIFIC DIARRHEAL DISEASE OF INFANCY

As noted earlier, almost all cases of HD in infants are produced by diarrheal disease. Thus, the epidemiology of HD reflects to some extent the epidemiology of this underlying cause, and some sense of the occurrence and distribution of infantile diarrheal disease is necessary to place HD in its proper perspective.

In many parts of the world, diarrheal disease is the single largest contributor to infant mortality and causes a formidable number of deaths. Diarrheal disease caused 645 infant deaths in the United States in 1977, a toll exceeded only by pneumonia among infectious causes in the postneonatal period,[34] The age of highest risk in the developing world seems to be the weaning period when infants are exposed for the first time to a multitude of infectious agents capable of causing toxic enteric manifestations. At this time, attack rates may reach 275/100 children per year, and mortality 50/1,000 children per year.[35] As might be expected, attack rates vary with the degree of sanitation in the community, and mortality varies in relation to this factor, nutritional status, and possibly access to medical care.

No specific pathogen can be isolated from the majority of infants with diarrhea. In areas where known enteric pathogens such as *Salmonella*, *Shigella*, and parasites are endemic, the isolation of these in cases of infantile gastroenteritis rarely reaches 40%.[35] Nevertheless, epidemiologic evidence incriminates an infectious agent in almost all cases. Spread within families and institutions is notoriously common, and a definite incubation period is usually found. It is also well known that a multitude of agents not considered classic enteric pathogens can cause gastroenteritis. Adenoviruses and several strains of echovirus

Renal unresponsiveness to antidiuretic hormone
Lack of antidiuretic hormone

have been known to cause localized outbreaks among infants.[36-39]

In recent years, attempts to isolate specific agents in infantile diarrhea have been more productive. Two agents, each with properties making its identification difficult, have been implicated. Toxigenic strains of *Escherichia coli* have been found increasingly often in the stools of patients with diarrhea as the technique for identifying *E coli* exterotoxin has become more prevalently used. A considerable proportion of traveler's diarrhea is now thought to be of this origin.[40,41] In infants, studies have occasionally implicated this agent.[28,42,43]

The "reovirus-like agent" has also been implicated in many cases of diarrhea in infants.[44-47] This circularly shaped virus, also referred to as rotavirus or orbivirus, has been identified so far only by electron microscopy and has not yet been grown successfully in the laboratory. The evidence that this may be the single agent most responsible for infantile diarrhea is beginning to accumulate.[48-51]

EPIDEMIOLOGIC FEATURES OF HYPERNATREMIC DEHYDRATION

Sources and Limitations of Data

As diarrheal disease is not reportable to government sources, what little epidemiologic knowledge we have about HD must be based on the series of cases described in the literature.

*From Koch et al.[23]
†Periods during which entire stool was collected ranged from two to five days, with exception of the study of Finberg et al,[88] where data represents single aliquots of stool collected at time of admission from infants with diarrhea.

Some of these series are reports of infants with HD and their characteristics; others report series of cases of diarrheal dehydration and contrast the characteristics of HD with NHD. The latter category of study is more useful and unfortunately rarer. A list of several studies of both kinds can be found in Table 3.

Some caveats apply to the interpretation of data reported in all of the studies. First, different categories of infants are included under the term HD. Although a cutoff point of 150 mEq/L is used rather uniformly, some studies describe all infants in whom such a value was found, others describe only infants with diarrheal dehydration as a predisposing cause.

Second, all reported series consist of

hospitalized cases only. It is possible that an infant may die before arriving at the hospital and that his death may be attributed to other causes.[52] It is unlikely, however, that clinically important cases otherwise escape medical attention, at least in the developed world. The most important problem is that different criteria for hospitalization and drawing of electrolytes operate in different series.

Third, HD is generally reported as a percentage of dehydrated infants. Thus, it is a conditional probability with the denominator population being all dehydrated infants hospitalized. From these data, we can make no definite inferences as to the true incidence of HD. Nevertheless, this conditional probability is of great interest in itself, as it tells the risk of HD developing given the stress of diarrheal dehydration.

Environmental Attributes of HD

Geography.—An important conclusion to be drawn from the data in Table 3 is that the proportion of dehydrated infants found to be hypernatremic is much higher in North America and Great Britain than in the less developed countries of Africa and Asia. The report from Nigeria is an exception, but it is worth noting that it comes from an urbanized community—Lagos. Within the United States, there seem to be some areas with higher incidences than others, but the numbers of cases reported, for example in the Minneapolis study, preclude any firm conclusions. The possible explanations for this variation are many, and will be considered under the appropriate categories.

Infecting Agent.—There is little evidence that there are differences in the agents likely to be isolated from HD and NHD. Certain of the bacterial pathogens may, however, be associated with a tendency to NHD. Cholera, for example, produces a loss of essentially isotonic fluid in large volume and, thus, usually produces either isonatremia or hyponatremia. There is some evidence that enteropathogenic *E coli* may also be more likely to be associated with NHD as the stool electrolyte level tends to be somewhat higher in this disease than in nonspecific diarrhea.[53] Jacobs and Holzel,[5] in reporting a hospital outbreak of gastroenteritis caused by *E coli* serotype 0114, noted that the incidence of HD was much lower (0/21) in the affected infants than in infants admitted for diarrheal dehydration during the same period of time (9/16). Attribution of these differences to the difference in isolated agents is limited by the fact that the infants affected by *E coli* in this study had all been hospitalized, many with chronic illness and some of them malnourished. The affected infants also had a greater incidence of vomiting, although the effect of vomiting on serum sodium concentrations is variable.

An agent may be more likely to cause HD for reasons other than its effect on the composition of gastroenteric losses. Organisms producing fever and hyperpnea might be expected to be associated with a greater tendency with hypernatremia because of the increased water losses. To my knowledge, however, no series has been reported in which a comparable group of infants with HD and NHD have been shown to have any differences in the likelihood of having any specific organism isolated from them nor even in the likelihood of having an organism isolated at all. Early studies of infants with diarrhea in which the techniques necessary for the identification of reovirus-like agents and *E coli* enterotoxin were used did not commonly report on serum sodium levels in affected or unaffected infants.[42,44,46,47] More recent studies describing the clinical picture in diarrheal disease caused by the reovirus-like agent do not report any particular predisposition to hypernatremia.[48-51] Only one of 27 infants from Toronto studied by Tallett et al[51] had a serum sodium concentration greater than 150 mEq/L. In the series by Rodriguez et al,[49] 5% of the infants with reovirus diarrhea were hypertonic, whereas 16% of the infants with diarrhea from whom reovirus was not isolated were hypertonic, a difference that is statistically significant. In this study, infants infected with reovirus were somewhat younger, which might explain a greater propensity to electrolyte disturbance.

Feeding History and Nutritional Status.—Nutritional and dietary differences between the developing and underdeveloped world seem likely candidates for variables capable of explaining the difference in relative incidence of HD. It has been known for some time that malnourished infants are predisposed in general to hypoelectrolytemia, and much work has been done in attempting to elucidate the biochemical derangements in malnutrition.[23,54-58] In the underdeveloped world, a large proportion of infants with NHD have hyponatremia even without the isolation of organisms likely to cause considerable sodium losses.

If undernutrition predisposes to hyponatremia, does overnutrition in some sense predispose to hypernatremia? As noted earlier, a pathogenetic mechanism does exist by which the protein and electrolyte content of an infant's diet, its renal solute load, might, if present in excess, cause renal losses of water that could predispose to HD. There is also ample evidence that both protein and sodium are present in the diet of US infants in rather large amounts. The survey by Filer and Martinez[59] of 4,000 representative 6-month-old infants found that the mean protein intake in grams per 1,000 calories of intake was more than twice the National Research Council's recommended allowance. This report also noted that although caloric intakes for South Korean infants were from 74% to 85% of those of US infants, protein intakes were only 32% to 43% of those of US infants. Sufficient publicity has been given to the salt content of infant foods so as not to require a comprehensive review here. Suffice it to say that mean sodium intakes in infants in the United States increase at a greater rate than weight or caloric intake during the first year of life, and at one time averaged about 6 mEq/kg/day, or about five times what would be provided in a breast-milk diet.[60,61] It is likely that recent changes in infant food salt content have reduced these figures. Although some of the excess protein and sodium in US infant diets is undoubtedly incorporated into the greater body

mass of US infants, much of it must be excreted in the urine, drawing water with it.

Do infants with HD have a different dietary history from infants with NHD? Although this would seem a logical question to ask, surprisingly little attention has been given to the dietary patterns of dehydrated infants. Some reported series of cases have presented data on the intake of the infant just prior to admission. Franz and Segar[25] showed that in their series infants with HD were more likely to have been treated with a powdered oral electrolyte solution (Lytren), which has a sodium concentration of 50 mEq/L when properly constituted. This association was also noted by Colle and Ayoub.[2] After these reports and an editorial by Finberg,[62] the electrolyte solution was adjusted to provide a sodium concentration of 25 mEq/L when reconstituted. A number of other studies, however, failed to show an association between HD and excessive salt intake prior to admission.[4,63] Berenberg et al[64] have shown that boiled skim milk, once commonly recommended for infants with diarrhea, may also predispose to hypernatremia. Thus, it seems clear that the nature of an infant's intake during his illness can influence his chances of becoming hypernatremic, although the evidence is slim that excess solute in the fluids prescribed for infants with gastroenteritis is now a highly prevalent causative factor in the United States.

That the diet generally fed to infants can produce hypernatremia is well known from the large number of cases of HD reported to have been caused by errors in formula preparation.[10,65-70] Outbreaks of hypernatremia in neonates associated with improper formula constitution have been reported from France and Spain.[71,72] Gross errors in formula preparation are easily recognized by history, but several British authors have suggested that smaller errors in formula preparation, such as using heaped rather than level teaspoons of dried formula, are much commoner than suspected.[67,73,74] These errors are almost always on the side of overconcentration rather than overdilution. Clearly, such errors are much more likely to occur when powdered formulas are used, and the fact that powdered formulas constitute less than 10% of the formula market in the United States[75] limits the application of this factor as a determinant of HD on this side of the Atlantic.

The question of whether diets not generally recognized to be harmful may place a dangerous load on the infant's kidneys has been raised by a number of investigators. The renal solute level of commonly used humanized milks is almost twice as high as that of breast milk, and that of cow's milk is three times as high.[76] Two studies in Great Britain have shown that a random urine osmolality is likely to be higher in a healthy breast-fed infant.[67,77] One of these studies[77] also showed that serum osmolality was higher in formula-fed infants than in breast-fed infants, and that it was higher still in infants of the same age who were receiving both formula and solid foods. Another British study was unable to reproduce these findings in serum osmolality, but did note a substantial difference in BUN levels, with formula-fed infants having higher levels than breast-fed infants.[78] To my knowledge, there is only one published report of HD occurring in an otherwise healthy exclusively breast-fed infant.[79]

These data are provocative but thus far the link between these findings and HD has not convincingly been made. Only one attempt to obtain data on the diets generally fed to infants with HD and with NHD has been made. Chambers and Steel[29] found a statistically significant correlation between the sodium concentration and the total osmolarity of the formulas generally fed to infants and their risk of having HD. Generalization from this study is, however, limited by the fact that the infants involved had an unusual age distribution for diarrheal dehydration, the mean age for the infants with HD being 2.2 months and that for infants with NHD being 1.8 months. The study period in this report was February to September, not the peak season for diarrheal dehydration in the United Kingdom, and thus the study might have selected atypical cases.

Temporal Variation.—No definite secular trend in the incidence of HD can be identified although it has been suggested that the disorder is more common than in the past. Some British authors have suggested that the incidence is now beginning to decline in Great Britain and have linked this decline to the greater use of humanized milks.[80-82] Given the ever-changing criteria for admission to hospital and determination of electrolytes, it is not possible to make any definite statements about such trends from the published literature.

There is a definite seasonal variation in infantile diarrhea, with the colder months being modal in the developed world. This in itself is interesting as in the past, summer was the season for diarrhea the world over. Both *Salmonella* and the enteroviruses have a predilection for the summer months, and it is possible that in the past, with poor sanitation, these organisms may have been important causes of diarrhea.

Data conflict on the question of whether HD and NHD have a different seasonal variation, but the weight of the evidence seems to be on the side of a winter-time peak for both disorders, which is more pronounced for HD, at least in the United States. Bruck[27] analyzed the monthly breakdown of serum sodium levels in dehydrated infants during a 13-year-period in Buffalo, NY, and found a statistically significant difference in the proportional incidence of HD in winter as opposed to summer, with a higher percentage of dehydrated infants found to be hypernatremic in the winter months. The proportion of HD in each winter month varied little, ranging from 36% to 49% of all dehydrated infants. Since the number of admissions in the winter months was four times as high as those in summer months, the peak incidence for both forms of dehydration was in the winter. Rosenfeld et al[8] found HD in 63% of the infants with diarrhea hospitalized for diarrhea in December, January, and February in contrast to a 23% proportion over the entire three-year period examined in their study. In contrast to this experience is the

aforementioned study by Chambers and Steel[29] who found a 60% rate of HD in the period February to September. Macaulay and Blackhall[4] were unable to find any differences in seasonal occurrence between patients with HD and NHD in their study. Winter seems to be the peak period for reovirus infection,[47,51] and it is thus tempting to consider a possible link between HD and this organism, but, as noted, reports published thus far do not support such an association.

Host Characteristics in HD

Most series do not report noticeable age differences in patients with HD and NHD, and two authors specifically note that the mean age of patients was the same.[1,4] In eight series in which the mean age of patients with HD was given, it ranged from 6 to 9 months in seven of them, and was 2.2 months in one series from Great Britain. Thus, in most instances it seems that HD occurs in infants who are in the same age range as most infants with diarrheal dehydration, although occasionally younger infants may be involved, particularly if formula errors are operative.

No consistent trends have been noted in any studies in race or ethnicity of patients with HD, and socioeconomic features have rarely been examined. Geographic variation cannot be explained by different racial susceptibility as most US series contain a substantial proportion of both black and white infants.

Many studies of HD have noted a greater tendency for such infants to be febrile. In one study,[4] this difference was statistically significant. One might conclude that a virus causing fever as well as diarrhea would be more likely to cause HD. On the other hand, it should be remembered that hypernatremia itself may cause fever. Victims of the epidemic of salt poisoning in Binghamton, NY, were uniformly febrile although the cause was clearly noninfectious.[9] High-protein feeds given to premature infants have been associated with fever and lethargy.[63] This phenomenon has been termed protein fever and is thought to be mediated by hyperosmolarity (H. H. Gordon, MD, oral communication, Jan 14, 1977).

Respiratory rate has not often been contrasted in infants with HD and NHD but has occasionally been found to be higher in infants with HD. Much the same argument applies as with fever, as rapid grunting respirations were a hallmark of salt-poisoned infants.[9]

Is it possible that infants with HD are simply the most severely dehydrated? There is some evidence that in series of dehydrated infants there is a tendency for the hypernatremic infants to be more severely affected. Application of clinical criteria to the assessment of dehydration would be expected to produce a bias in favor of declaring infants with NHD the most dehydrated for the reasons outlined in the first part of this article. This trend was found in the series by Macaulay and Blackhall[4] who noted that infants with HD were more likely to be classified as having mild dehydration than infants with NHD. Ironside et al,[6] on the other hand, found that 89% of their infants with HD were classified as moderate or severe in degree of dehydration, as compared with 61% of the infants with NHD. In the series by Colle and Ayoub,[2] mean BUN levels were higher in the group with HD. However, BUN levels may not be purely indicative of dehydration in this disorder, as hypernatremia has a well-established nephrotoxic effect.[84] An interesting set of data is available from a recent publication on CSF osmolarity in HD by Habel and Simpson.[85] This article records serum sodium concentration, BUN level, and the volume of fluid deficit of dehydrated infants, the latter calculated by comparing infants' weights on admission with their weights when rehydrated. The data show a slight tendency for the most severely hypernatremic infants to be the most dehydrated, but the relationship is far from linear. By way of contrast, Rodriguez et al[49] found that reovirus diarrhea was both more likely to cause dehydration and less likely to cause hypernatremia than nonreovirus diarrhea. Although infants with HD are probably on the whole somewhat more dehydrated than infants without HD, the data of Habel and Simpson show that severe dehydration is not a prerequisite for hypernatremia since 50% of this series of infants with HD were less than 10% dehydrated.

Classic teaching is that the tonicity of the body fluids in diarrheal dehydration relates directly to the tonicity of the losses in the stool and/or vomitus. Thus, stool electrolyte values might be expected to differ in HD and NHD. As noted earlier, however, other factors would be expected to enter into the equation, especially in small infants. In cholera, it has been known since at least 1832 that there is a direct relationship between stool and serum sodium.[86] It has even been shown that in pediatric cholera, stool sodium concentration is lower than in adult cholera and, as a consequence, that serum sodium levels are somewhat higher than in adults.[87] It comes somewhat as a surprise then to discover that for nonspecific diarrhea of infancy no such relationship can be documented. Finberg et al[88] have shown that over a range of sodium concentration in the serum from 118 to 170 mEq/L no relationship was found to the stool sodium concentration in dehydrated infants. This lack of a relationship was also found by Bruck et al[39] in a smaller series. Table 6, from Kooh and Metcoff,[23] shows that in several studies from different parts of the United States, performed on infants on different diets, stool sodium concentration in diarrhea tended to be remarkably similar. The only study that reports on stool sodium concentration in reovirus diarrhea[51] found it to be slightly lower than the figure given in the review by Kooh and Metcoff. The fact that the infants in this study were not particularly predisposed to HD supports the conclusion that the variance in serum sodium concentration in diarrheal disease is not generally mediated through the stool sodium concentration.

Some other observations have sporadically been made about infants with HD and have been speculated to be causative. A few authors have noted that infants with HD are more likely to have an explosive onset of their disease. Of course, cholera has

the most explosive onset of any infectious diarrhea, but does not produce hypernatremia. Nevertheless, the principle involved may be that in diarrheas of rapid onset serum sodium concentrations may reflect stool losses more closely. If infant diarrhea is by and large hypotonic as noted in Table 6 by Kooh and Metcoff,[23] this may indeed be an explanatory variable. Unfortunately, carefully controlled comparative data on this variable have not generally been obtained.

Noting the high incidence of the disorder in the winter months, some authors have speculated that low-humidity heating systems may be a factor.[8] No actual observations have been made to confirm or deny this.

CONCLUSIONS AND DIRECTIONS FOR FUTURE STUDY

Hypernatremic dehydration is almost certainly a multifactorial disease that can be produced by a variety of pathways or combinations of pathways. From the limited epidemiologic information available only rather tentative conclusions can be drawn. It seems unlikely that the source of variance in serum sodium concentration in dehydration is due to differences in the infecting agent. The fact that both HD and NHD have peak incidences in the same age group at the same time of year suggests that a single agent is operative and that the differences in sodium concentrations among infants relates to a difference in host response. This difference may be the particular form the illness takes in some infants as opposed to others, the manner in which it is dealt with, or some underlying difference in the host himself or herself. A strong line of evidence implicates dietary factors as possibly producing a host that is unusually susceptible to HD, but definite links between these two variables have not been established.

Future research efforts should be directed at the elucidation of the relationship between HD and dietary experience, as well as between HD and any of the more recently discovered enteric pathogens. It would be of especial interest to know more about the patterns of electrolyte disturbance in infants from whom the reovirus-like agent is isolated. Such studies should be based on information prospectively collected from infants with both HD and NHD selected in as random a fashion as possible. Clinical and demographic data should be obtained on both groups of infants so as to ascertain their comparability and to stratify data along lines that seem appropriate, eg, degree of dehydration, etc. If the dietary experience is an important causal variable in the production of HD, it is a variable possibly amenable to modification. Thus, searching for this association has the practical importance of possibly leading to a means of preventing this disorder and thereby causing a small, but not necessarily trivial, reduction in the prevalence of childhood handicap.

Part of this work was done while Dr Paneth was a Fellow in Human Developmental Biology at the Albert Einstein College of Medicine, New York, and supported by training grant T32-HD07053 from the National Institute of Child Health and Human Development.

Neonatal von Willebrand's Disease: Diagnostic Difficulty at Birth

von Willebrand's disease (vWD) is an inherited disorder of bleeding, which is characterized by easy bruisability, mucosal hemorrhages, excessive posttraumatic bleeding, prolonged skin bleeding times, and quantitative or qualitative defects of the factor VIII molecular "complex." von Willebrand's disease and the structure and physiology of the factor VIII molecule have recently been reviewed.[1-3]

We studied a 7-month-old affected male infant whose father and paternal grandfather were known to have vWD. Because of his family history, the child's plasma was studied at birth, at 6 months of age, and after the intravenous (IV) administration of cryoprecipitate. Our findings emphasize the difficulty in establishing the diagnosis of vWD in the immediate postnatal period.

Report of a Case.—The patient is a 7-month-old boy, product of an uncomplicated 40-week gestation, born to a 19-year-old, blood group O, Rh-positive, gravida 1, para 1, abortus 0, hemostatically normal woman. Labor was induced with IV vasopressin five hours after spontaneous rupture of the membranes. Seven hours later, signs of fetal distress appeared and the patient was delivered by cesarean section. At birth, the child was dusky and had a good cry. The one- and five-minute Apgar scores were 8 and 9, respectively. Birth weight was 3,530 g. Results of physical examination were normal. His neonatal course was uneventful and diagnosis was made on the fifth hospital day.

His father and paternal grandfather have histories of life-long bleeding and are known to have vWD (Table). Because of the family history of vWD, cord blood (IgG level, 380 mg/dL; IgM level, 50 mg/dL) was obtained immediately after birth and the infant's plasma levels of factor VIII anticoagulant (FVIII-AGH), factor VIII-related antigen (FVIII-AGN), and factor VIII-risotocetin cofactor activity (VIII-vWF) were measured. At 6 months of age, he was noted to have bilateral inguinal hernias that required surgical correction. Laboratory studies at that time showed the presence of vWD (Table).

• Immediately prior to, and at six-hour intervals after surgery, 1 unit of cryoprecipitate was infused. The child's postoperative course was uneventful and he was discharged 48 hours after surgery.

Measurement of the template bleeding time, of levels of FVIII-AHG, FVIII-AGN, and FVIII-vWF, and of two-dimensional crossed immunoelectrophoresis of plasma FVIII-AGN was performed by previously described techniques.[4] Our laboratory normal values were determined by assaying plasma from 55 normal adult persons against our standard pool (20 adult donors).

Data on the patient's father and paternal grandfather revealed that both have reduced plasma levels of FVIII-AHG, FVIII-AGN, and FVIII-vWF, and prolonged template bleeding times (Table). Cord blood obtained at birth from the patient had normal plasma levels of FVIII-AHG, FVIII-AGN, and FVIII-vWF. However, when studied again at the age of 6 months, his plasma levels of FVIII-AHG, FVIII-AGN, and FVIII-vWF were found to be decreased (Table). In addition, his plasma FVIII-AGN had an increased mobility on two-dimensional immunoelectrophoresis.

After transfusion of 1 unit of cryoprecipitate on the day prior to surgery, his plasma FVIII-AHG, FVIII-AGN, and FVIII-vWF levels rose to normal. The FVIII-AHG level remained within the normal range during the entire 24-hour period of observation. The plasma levels of FVIII-vWF and FVIII-AGN returned to the pretransfusion values by eight hours and 24 hours, respectively. Bleeding time studies were not performed.

Comment.—von Willebrand's disease is a heterogenous disorder. Some patients have absent or reduced levels of FVIII-vWF, FVIII-AGN, and FVIII-AHG. In others, a defect in FVIII-vWF is associated with normal FVIII-AGN and FVIII-AHG levels.[5] Those persons may also have an FVIII-AGN whose mobility on two-dimensional crossed immunoelectrophoresis is increased.[6] Bleeding times vary and may not correlate with the levels of FVIII-AHG, FVIII-AGN, or FVIII-vWF.

Our patient's vWD is characterized by reduced levels of FVIII-AHG, FVIII-AGN, and FVIII-vWF, and an abnormal electrophoretic mobility of his plasma FVIII-AGN. In addition, he responded to cryoprecipitate infusion with the prolonged rise in FVIII-AHG characteristic of vWD.[7] His affected father and paternal grandfather have clinical bleeding, prolonged template bleeding times, and reduced FVIII-AHG, FVIII-AGN, and FVIII-vWF levels. Of interest was the observation that the child's plasma FVIII-vWF and FVIII-AGN levels fell after transfusion at rates similar to those described in adult patients with vWD.[8]

Normal term infants are reported to have normal cord blood levels of FVIII-AHG and FVIII-AGN, and, perhaps, slightly reduced levels of FVIII-vWF.[9] Of concern is that our patient's plasma levels of FVIII-

*FVIII-AHG indicates factor VIII coagulant level; FVIII-AGN, factor VIII-related antigen; FVIII-vWF, factor VIII-ristocetin cofactor activity.
†ND indicates not done.

AHG, FVIII-AGN, and FVIII-vWF were normal at birth. Those plasma levels may rise in adult vWD patients in response to "stress," pregnancy, administration of epinephrine, or the infusion of the synthetic vasopressin analogue 1-deamino-8-D-arginine vasopressin without an improvement in the bleeding time.[1] It is possible that at birth our patient's normal plasma levels of FVIII-AHG, FVIII-AGN, and FVIII-vWF were in response to the vasopressin used to induce labor, or to his prenatal "stress."[10] These may then have obscured the diagnosis of vWD. Our observation suggests that elective diagnostic studies and surgical procedures in neonates suspected to have vWD should be delayed, when possible, beyond the neonatal period.

Munchausen's Syndrome

Munchausen's syndrome, or chronic factitious illness, is the diagnosis applied to a patient who chronically seeks admission to hospitals, with apparently acute illnesses. These are due to self-inflicted, self-mutilative lesions associated with misleading physical and laboratory findings as well as an exaggerated, distorted medical history. These patients are frequently dramatic in their presentation of symptoms and are often sophisticated and knowledgeable in medical terminology. As a result of their confusing, skillful mimicry, they may be subjected to many unnecessary medical and surgical procedures.

Most pediatricians have encountered malingering or such simulated symptoms as factitious fever in children and adolescents. Major chronic factitious illness or Munchausen's syndrome is very rare in the pediatric age group.[1]

Report of a Case.—The patient is a 15½-year-old girl who had been adopted at age 2 years in Japan and reared in Hawaii as an only child. Her first major hospitalization occurred at age 15½ years for headache and abdominal pain. These symptoms appeared one month after the family home was burglarized, after which the patient allegedly received threatening phone calls and reportedly was raped. A subsequent hospitalization occurred six months later for anxiety symptoms, induced by repeated threats from the assailant. Over the next year, numerous physician contacts and hospitalizations took place.

At 17 years of age, she was hospitalized for removal of an exostosis of the foot. Six months later, the patient was readmitted with a diagnosis of severe hysterical psychotic reaction and probably dissociative reaction precipitated by accumulated emotional stress. An EEG showed nonspecific abnormalities, otherwise the results of the medical workup were negative.

During the next several years, the patient was seen by a series of practitioners and specialists for a variety of complaints, the most serious of which was suspected septic arthritis of the knee that resulted in hospitalization. *Proteus* and *Escherichia coli* grew from an aspirate of the left knee. Four months after her first septic joint, she was readmitted for a recurrence. Again *E coli* grew from the aspirate. On follow-up, the patient complained of morning stiffness and arthralgias without evidence of joint swelling and received high-dose aspirin therapy. Numerous episodes of septic arthritis of the left knee recurred from which *Staphylococcus aureus*, *E coli*, and *Klebsiella* were cultured.

Later, a synovectomy and meniscectomy were performed for chronic inflammatory synovitis. At 18½ years of age, the patient again had fever and knee pain; a diagnosis of rheumatoid arthritis was entertained, and she was referred to the Rheumatology Clinic at Kapiolani-Children's Medical Center in Honolulu. Temperature was 38.5 °C. Considerable pain on movement of the left leg was noted, and her left knee was inflamed and swollen with effusion. Routine laboratory studies, as well as extensive infectious, immunologic, and rheumatologic studies were normal except for a slightly elevated anti-DNA antibody level. Culture of the joint fluid was sterile. A psychiatric consultant evaluated the patient to be a "typical, stable adolescent, without gross psychopathology."

During the next several months, the patient was hospitalized for recurrent joint pains, a suspected seizure disorder, and rectal and vaginal bleeding. A dilation and curettage (D&C) was performed. In yet another episode, the patient experienced loss of consciousness, followed by a glove-like anesthesia of the arm, and later a transient paralysis developed. During a subsequent hospitalization for a possible seizure, she complained of multiple joint pains. Her C-reactive protein and rheumatoid factor were both weakly positive.

At 19½ years, the patient was readmitted for a septic *right* knee. She gave a history of persistent morning joint stiffness of hands and shoulders for which she had been receiving high-dose aspirin therapy from her private physician. She also gave a three-week history of redness and burning in her right eye for which she had received prednisone. On physical examination, the joint was swollen, and an effusion was present. Four puncture marks lateral to the patella were noted. *Klebsiella* grew from an aspirate of the knee. Four blood cultures were negative. An extensive infectious, immunologic, and rheumatologic workup was again repeated, and results were negative.

One month after discharge, the patient returned to the center with evidence of a septic right knee, and *Klebsiella* again grew from the aspirate. Two needle marks, presumably the result of aspirations performed by her private physician, were noted. On the patient's 23rd hospital admission one month later, she complained of neck stiffness, dysphagia, and headache. At that time, she gave a history of two prior D&Cs. During the next eight months, she saw many physicians for various complaints and at 20 years of age was noted to have swelling above both wrists with associated needle marks. At this time, a syringe containing a feculent suspension was inadvertently discovered among her possessions.

In all, this patient experienced 23 hospitalizations, 13 major surgical procedures and, innumerable visits to many physicians before the correct diagnosis of Munchausen's syndrome was confirmed. Subsequently, while under psychiatric treatment, she

has recently been hospitalized for sepsis secondary to an intravenous injection of urine.

Comment.—The basic distinction between malingering, hysterical conversion reaction, and Munchausen's syndrome is often unclear. Most authorities agree that malingering is conscious, volitional, situationally appropriate behavior aimed toward clear secondary gains. It is often associated with a stressful environment; however, there are usually no major psychopathologic findings evident.[2] A conversion reaction is nonorganic illness in which the signs and symptoms are nonvolitionally simulated and secondary to unconscious drives.[3,4] Munchausen's syndrome is an underlying psychiatric disorder with an "addiction" to medical care. Organic illness is present that is self-inflicted. These medically sophisticated patients often have a bizarre history that is usually long, complex, dramatic, and plausible. They frequently are employed in an allied medical field or at least have had substantial contact with medical facilities. Motivation for their actions is usually obscure. Their need to be involved with physicians is an integral part of their personalities.[4]

In 1951, Asher named this syndrome after Baron Friedrich von Munchausen (1720-1790), a retired German cavalry officer, who wandered from town to town "telling tall tales."[5] The syndrome has been linked to many underlying psychiatric diagnoses, such as sociopathic personality disorder, schizophrenia, various psychoses, and hysterical neuroses. Early childhood trauma, possibly associated with a medical setting or some form of deprivation, is often elicited.[2,6] There may be an impressive variety of symptoms and signs. The patient's medical contacts are usually extensive. One adult patient was the subject of 16 case reports in the literature with an extensive spectrum of manifestations.[2,5,7]

Of the three reported cases in the pediatric age group, one was that of a severely disturbed adolescent girl with a long, complicated history of uterine bleeding during and after pregnancy, hematemesis after consuming blood, massive self-bloodletting, repeated anemia and shock, home storage of large quantities of blood, and hematuria from urethral trauma.[6,8] The second case was that of a 15-year-old boy who simulated an enterovesicular fistula by contamination of his urine with feces and food, at times by retrograde injection into his bladder.[9] An adolescent who produced recurrent parotitis by insufflation of his Stensen's ducts has been described. Munchausen's syndrome by proxy has been reported in the pediatric age group.[10,11] Here, children are the victims of factitious illness inflicted on them by parents or caretakers.

The diagnosis in our case was difficult because of the patient's seemingly genuine complaints and perplexing findings. This girl was an excellent student, was involved in extracurricular activities, and had worked with arthritic patients in an orthopedist's office for a year as a physical therapy aide. She was well read, familiar with medical procedures and terminology, and highly informed on the subject of rheumatoid arthritis, the symptoms of which she incorporated in her presentations. However, the organisms cultured from her joint aspirates were highly atypical for septic joints in this age group and provided the clue to the correct diagnosis.[12,13]

Once exposed, adult patients usually leave the hospital abruptly and exhibit some form of contempt or antisocial behavior toward personnel caring for them.[14] Although it is easy to become frustrated managing a patient suspected of having factitious illness, these patients have a severe, life-threatening psychiatric illness requiring intervention. The rarity of Munchausen's syndrome in childhood and adolescence predisposes to diagnostic and treatment problems. Often there are associated moral, ethical, and legal dilemmas. The deviant physician-patient relationship contains no therapeutic alliance, and adult patients usually avoid psychiatric help. In minors, therapy can be enforced with parental cooperation. However, the parents themselves may undergo intense feelings of grief and helplessness. They may find the suggestion of chronic factitious illness in their child absurd, and bring litigation against physicians for unnecessary procedures performed on their child. Judicial intervention may be necessary to obtain proper protection and psychiatric treatment.

Munchausen's syndrome is rare and often belatedly considered as a possible diagnosis. The actual incidence is unknown. In the adolescent, accurate medical diagnosis is often obscured by behavioral and emotional problems, and depression with somatization. Making the diagnosis requires a high index of suspicion, close scrutiny of prior medical contacts, and effective communication among health care deliverers.

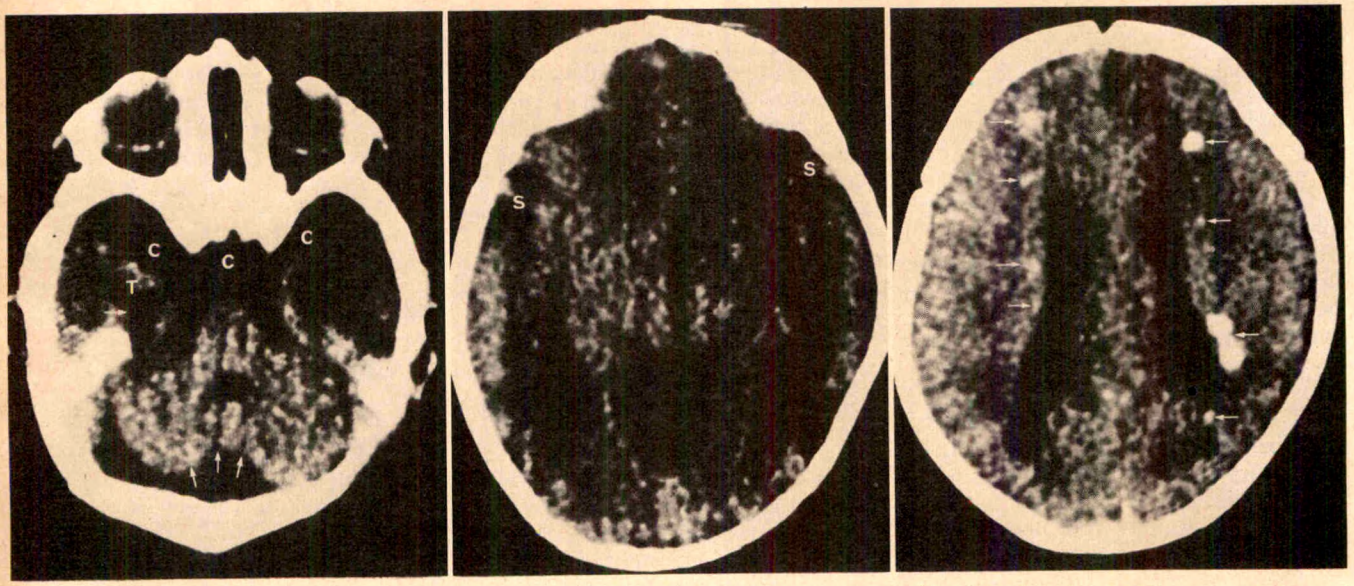
Computerized Tomography to Define CNS Involvement in Congenital Cytomegalovirus Infection

The most serious sequelae of congenital cytomegalovirus (CMV) infection involve the CNS. However, predicting the neurological outcome of a neonate with congenital CMV may be difficult unless severe CNS damage is already obvious at birth. Some severely affected babies with intrauterine growth retardation, hepatosplenomegaly, and other stigmata asso-



Computerized tomographic scan of infant with congenital cytomegalovirus infection done at 1 week of age showing cerebellar atrophy (arrows), dilated temporal horns (T) and enlarged cisterns (C) (left); large subarachnoid space (S) and hydrocephalus (center); and periventricular calcifications (arrows) (right).

ciated with CMV infection have normal intellectual development without detectable neurological deficits.[1] Neurological evaluation usually consists of a careful neurological examination and a roentgenogram of the skull to detect calcifications. We describe a newborn with proven congenital CMV infection who had a normal neurological examination and a normal roentgenogram of the skull; computerized tomography (CT) gave a more accurate picture of the severity of CNS involvement.

Report of a Case.—A full-term baby girl was born to a 28-year-old-mother who had a negative test for syphilis and a positive rubella titer. The baby weighed 2,110 g and had an Apgar score of 7 at one minute, and 8 at five minutes. Height, weight, and head circumference measurements were all below the fifth percentile. The head circumference was 35.0 cm and was proportional to the height and weight. Physical examination revealed a small-for-gestational age baby with marked jaundice, numerous "blueberry muffin"-type skin lesions, petechiae, and hepatosplenomegaly. Results of ophthalmologic and neurologic examinations and audiometry (behavioral response to pure tones) were normal. The peripheral WBC count was 7,700/cu mm; platelet count was 1,000/cu mm; and SGOT level was 98 IU/L (normal newborn value, 16 to 74 IU/L). Bacterial cultures of CSF, blood, throat, and stool were sterile or revealed no pathogens. Cytomegalovirus grew from viral cultures of urine and nasopharynx. Roentgenograms of the knees and wrists revealed metaphyseal rarefactions and "celery stalking" of the femurs and tibias consistent with intrauterine infection. A roentgenogram of the skull were normal; intracranial calcifications were not seen.

The baby's skin lesions, jaundice, heptosplenomegaly, and thrombocytopenia gradually resolved over a three-week period. Because of concern that severe thrombocytopenia may have predisposed the child to an occult intracranial hemorrhage, a CT scan was done (Figure). The CT scan showed mild hydrocephalus of the entire ventricular system. The subarachnoid space was voluminous, most noticeable over the left side of the cerebellum. There was no midline shift. Extensive periventricular calcium was identified.

At 1 month of age, the baby was seen in the outpatient clinic because of a generalized seizure, and treatment with phenobarbital was begun. At 5 months of age, the child had poor head control and did not roll over.

Comment.—Babies with congenital CMV infection who have microcephaly, seizures, or other findings of serious CNS involvement at birth have a poor prognosis in terms of future neurological development.[1-4] At least 75% will have microcephaly, psychomotor retardation, deafness, seizures, or other major cerebral dysfunction in later years.[5] Intracranial calcifications shown by plain roentgenograms of the skull suggest extensive brain involvement and are a poor prognostic sign[1,3] but are present in less than 1% of newborns with CMV.[4,5]

Our patient had clinical and laboratory evidence of severe, generalized CMF infection, but her neurologic examination and skull roentgenograms were normal in the neonatal period, suggesting a good prognosis. The CT examination was helpful in defining the true extent of CNS involvement.

Computerized tomography is more sensitive than plain films in demonstrating intracranial calcifications.[6-8] Also CT scan may reveal enlargement of the ventricular system and other abnormalities of the brain substance that are not visible on plain films. In the initial evaluation of babies with suspected intrauterine infection, particularly congenital CMV and toxoplasmosis, CT scan should be considered if plain roentgenographs are normal. The detection of calcifications or other brain abnormalities may be helpful in establishing the diagnosis of congenital infection early, and in clarifying the severity of neurologic involvement and thus the child's prognosis.

Heparin-Precipitable Cryoprecipitate in a Child With Cold Urticaria

Cold urticaria occurs occasionally in childhood and is associated at times with cryoglobulinemia, cold hemolysins, or cryofibrinogenemia. We describe here a patient who has cold urticaria associated with increased levels of heparin sodium-precipitable cryoprecipitate (HPC); to our knowledge, such a case has not been previously reported.

Report of a Case.—A 10-year-old girl was first seen in November 1976 because of urticaria accompanied by arthralgia. The previously well child had an intensely pruritic eruption of the feet develop after a swimming lesson. This resolved spontaneously within eight hours. Two days later, urticaria was noted from the waist to the feet after attendance at a night football game. Subsequent long outdoor exposures induced urticaria on the trunk, face, and legs and swelling of the fingers. Occasionally, the eruptions were accompanied by pain in the hips, shoulders, and right ankle. Cyproheptadine hydrochloride therapy did not diminish the urticaria. The history was unremarkable, including no joint symptoms or atopic manifestations. The family history was negative for atopic disease, urticaria, or cold intolerance.

Examination showed no abnormalities except for several small, nontender supraclavicular lymph nodes. There was no dermographism, and ice-cube application did not induce urticaria.

The ESR was 100 mm/hr; IgG, 2,800 mg/dL; IgA, 400 mg/dL; IgM, 85 mg/dL; IgD, 1 mg/dL; and IgE, elevated to 740 units. Normal or negative results were obtained for the following studies: complete blood cell count, platelet count, C-reactive protein, antinuclear antibody, lupus erythematosus cell preparation, DNA binding, latex rheumatoid factor, C3, C4, total hemolytic complement, VDRL, cold agglutinins, antistreptolysin O titer, urinalysis, fibrin split products, 12-factor automated chemical analysis, fibrinogen, prothrombin time, partial thromboplastin time, α_1-antitrypsin, and serum protein electrophoresis. Chest roentgenogram showed no abnormalities.

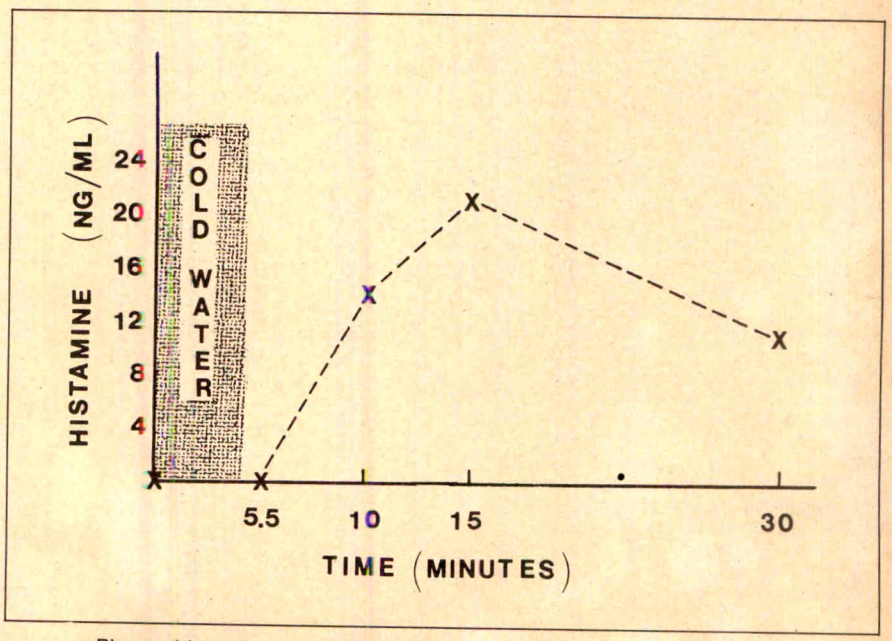
With careful protection against the cold, the patient remained clinically well during the subsequent year. However, the ESR remained greater than 50 mm/hr and plasma IgE continued to be elevated.

Special Studies.—Blood collected in preheated syringes and tubes was centrifuged at 37 °C. No notable precipitate developed in serum, heparinized plasma, or citrated plasma held at 37 °C for up to 72 hours or in serum or citrated plasma stored at 4 °C during this period of time. However, after 18 hours or more at 4 °C, heparinized plasma specimens were filled with a gelatinous precipitate. This HPC was washed twice in iced 0.05M phosphate buffer, with a pH of 7.4, and was redissolved by warming to 37 °C. The HPC specimens obtained on Nov 15, 1976, Nov 30, 1976, and Jan 26, 1977 showed total protein values (Lowry method) of 245, 125, and 200 mg/dL of plasma from which the precipitate was obtained. Respective fibrinogen measurements, by thrombin clotting time, in the redissolved HPC samples were 17, 25, and 39 mg/dL. A fourth specimen obtained in June 1977 showed an HPC value of 196 mg/dL. Trace amounts of immunoglobulins and complement components were detected in only one specimen. A drop of dilute thrombin solution caused immediate clotting. Immunoelectrophoresis also consistently showed a band of fibrinogen in all specimens, whereas immunoglobulins, C3, C4, and fibrin were not regularly identified. Polyacrylamide gel electrophoresis, with and without sodium dodecyl sulfate, showed a large number of components. The quantity of IgM, IgD, IgE, C3, and C4 and the hemolytic complement activity were as great in the precipitate supernatant of the second sampling (Nov 30, 1976) as in the whole plasma, and the IgG and IgA levels were only minimally reduced.

We measured HPC levels in ten other children aged 6 to 18 years. The range of values obtained was 40 to 152 mg/dL, with a mean of 95 mg/dL ± 29 SD. Thus, the patient's values on three occasions exceeded our normal values. Preferential adherence of IgE to the patient's HPC could not be demonstrated in experiments where IgE labeled with iodine 125 was added to the heparinized plasma before storage in the cold. Toluidine blue stained the well-washed cryoprecipitate, suggesting either adherence or incorporation of heparin into the precipitate.

Immersion of the left forearm in an ice water bath produced a substantial increase in the plasma histamine level[1] in venous blood drawn from the left antecubital fossa (Figure). No important change was observed in values for plasma hemolytic complement, C3, or C4 during this procedure. Changes in the HPC level were not measured. No substantial histamine release was observed in vitro at 4 °C by incubating the patient's leukocytes with her own or normal plasma or by incubating normal leukocytes with her chilled plasma.

Comment.—Hives associated with cryofibrinogenemia have been reported only rarely, though swelling of the extremities in infants has been noted.[2] In these cases, a precipitate occurs when incubating either citrated or heparinized plasma in the



Plasma histamine levels after immersion of an extremity in ice water.

cold.[3] Cryoprecipitation of plasma only in the presence of heparin is characteristic of HPC. Stathakis and Mosesson recently demonstrated that cold insoluble globulin (CIg), a normal plasma glycoprotein, is the essential element for heparin-induced cryoprecipitation of plasma.[4] However, fibrinogen substantially augments the process by its affinity for CIg. When screening more than 700 individuals for HPC, Smith found the highest values in patients with inflammatory conditions and advanced neoplasms.[5] The cause for the HPC in our patient cannot be determined from the available information since repeated studies failed to document the presence of any connective tissue or neoplastic disease. In addition, the relationship between the child's HPC and cold urticaria is uncertain. No evidence was found for complement activation, as occurs in some cases of cryoglobulinemia.[6] Other possibilities include the involvement of IgE, as in some cases of idiopathic acquired urticaria,[7] or the release of histamine from cutaneous mast cells[8] by this particular HPC. A chance association also cannot be excluded. Screening larger numbers of patients with cold urticaria for HPC may help to clarify this matter.

Ring Chromosome 15 and Failure to Thrive

Ring chromosomes are rare in man. Friedrich and Nielson[1] could not find one ring in the compiled data of the cytogenetic screening of 31,801 consecutive live-born children. Hecht and Vlietinck,[2] as well as Zdansky et al,[3] claim that the phenotypic and cytogenetic differences among even "identical rings" do not permit an accurate delineation of an identifiable syndrome. On the other hand, certain ring chromosome syndromes (ring 1, 6, 9, 13, 15, 21, and 22) appear already in textbooks[4] as separate clinical entities. To solve the controversy, more case reports seem warranted. Therefore, we discuss an infant with ring 15.

Report of a Case.—This girl was a product of the second pregnancy for her mother, who was 161 cm tall and 27 years of age at that time. The father was 168 cm tall and 35 years of age. Illness, exposure to drugs, and roentgenograms during the pregnancy were denied. The delivery was by spontaneous breech at 43 weeks' gestation. The birth weight was 2,850 g (the first-born brother weighed 3,150 g). The length was 48 cm and the head circumference was 33 cm. The Apgar scores were recorded as 7 at one minute and 9 at five minutes. No prenatal problems were encountered but several stigmata were noted: two small nevi flammei on the forehead; a port-wine mark, 2 × 1.5 cm, on the right forearm, three small café au lait spots in the left lower axilla and a larger one, 4 × 3 cm, on the left foot, and high-arched palate. At the age of 4 months, the child was hospitalized for "failure to thrive" with poor appetite, weight loss, occasional vomiting, and fever. Her weight was 5,400 g (10th percentile), length was 55 cm (below the third percentile), and the head circumference was 37 cm (below the third percentile). There was nothing striking in her appearance. Chest, cardiovascular system, abdomen, and genitals were unremarkable. Generalized mild hypotonia was present. Deep tendon reflexes were +2 all over. The stigmata recorded at birth were less conspicuous.

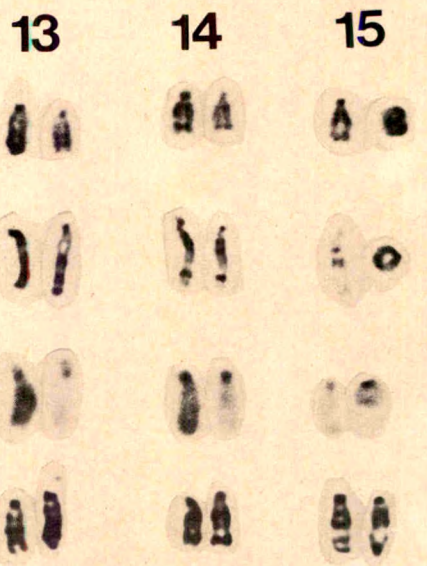
The dermatoglyphic pattern showed nine whorls and one ulnar loop. Axial triradii were in the t′ position with a bridged simian crease on the right palm only and distal loops in both third interdigital areas. Hallucal areas showed distal loops; the great toes had arches (mother and brother had similar dermatoglyphics but no simian crease).

The evaluation was nondiagnostic, the fever subsided, appetite improved, and the child was discharged home, gaining slowly in weight.

Psychological testing was done at 7 months of age. On the Bayley Scales of Infant Development, the mental age was 5 months and the motor age was 4 months; this was interpreted as mild to moderate delay in psychomotor development. Height and head circumference were below the third percentile—59 and 38.5 cm, respectively; weight was 6,300 g (third percentile).

Cytogenetic Studies.—Slides were made from peripheral blood lymphocytes of the patient and from the mother on two occasions. The mother had a normal karyotype. The father could not be studied. Seventy-five mitoses were studied: 70 of them showed 46 chromosomes with D-group chromosome replaced by a ring. The trypsin Giemsa banding technique demonstrated that the ring was formed by one of the number 15 chromosomes—46,XXr(15). It appeared that only tiny pieces of both the short and the long arm were missing. As suggested by the bands on the ring, the breakage point on the long arm was on the terminal, telometric part-q25. The short arm was not seen, which implied that the breakage point was at p11. The quinacrine fluorescent banding confirmed this impression. The C banding demonstrated one centromere on the ring. Two mitoses showed a dicentric ring in figure 8-shaped formation. One mitosis demonstrated the ring unfolded (Figure).

In none of the mitoses was the ring found in satellite association. This sug-



Partial karyotype of the patient demonstrating D-group chromosomes with centromere on ring 15, unfolded ring, and figure 8-shaped dicentric ring.

gests that the breakage point on the short arm was at p11 with the loss of the nucleolus organizer region. The latter region is known to be responsible for satellite associations for the acrocentric chromosomes in metaphase. The origin of the ring chromosome could not be determined cytogenetically.

Comment.—To the best of our knowledge, there are reports of nine patients with ring 15.[5-13] Failure to thrive was the hallmark in all those patients and growth retardation was present at birth. In our patient, however, the latter was not present. The patient of Emberger et al[6] was born at 34 weeks weighing, 2,250 g; thus, his failure to thrive also could be considered of postnatal onset. Microcephaly has been encountered in most of the patients[5,6,8,10-13] and is present in our patient as well. Mental retardation has been found in the majority of the cases.[5,6,8,11,13] The patient described by Forabosco et al[7] was considered to be of normal intelligence but she has not had formal testing and was only 16 months of age at the time of the report. The patient of Fujita and Matsomoto[12] had borderline intelligence. Based on the psychomotor delay in our patient, mental retardation should be expected. The stigmata in all patients were few and rather nonspecific. Actually, the only consistent finding was the absence of true dysmorphia.[4] Micrognathia was found in three patients.[8,11,13] Hypertelorism was claimed by three authors.[8,9,12] Including our patient, café au lait pigmentations were found in three cases.[10,12] Brachymesophalangy was seen in two patients.[7,11] A variety of stigmata was encountered just once. Major anomalies have been seen in several patients: congenital heart defects in three,[5,12,13] pyloric stenosis in one,[7] renal anomaly in one,[13] and hydrocephaly with amyotrophy in another.[8] Forabosco et al[7] and Schmid et al[11] reported the dermatoglyphics in detail without finding a characteristic pattern; other authors reported them as normal.[6,8,10,12] Our patient demonstrated only a bridged simian line in addition to the dermatoglyphic pattern characteristic for first-degree relatives examined by us.

Antenatal and/or postnatal growth deficiency may be the sole major sign of some of the newest cytogenetic syndromes, ring 15 included. Pediatricians caring for patients with failure to thrive that remains of unknown cause despite adequate workup should consider chromosomal abnormality. With banding techniques, a karyotype may demonstrate ring 15 or some other ring chromosome, such as ring 1, ring 6, or even partial 8p trisomy, as the reason for the growth deficiency.

Massive Intracranial Air Embolism: A Complication of Mechanical Ventilation

Mechanical ventilation in the management of neonates with respiratory distress syndrome has been extended to include the very premature infant weighing less than 1,001 g.[1] In spite of the new techniques and improved understanding of mechanical ventilation, there have been a number of complications.[2-5] These include pneumothorax, pneumomediastinum, pneumopericardium, pneumoperitoneum, venous and/or arterial air embolism, pulmonary interstitial emphysema, pseudocyst formation, and bronchopulmonary dysplasia. This communication reports yet another complication, an unusual case of massive intracranial air embolism in a premature infant.

Report of a Case.—The patient was a 780-g male neonate, born spontaneously at 24 weeks' gestation. The Apgar scores at one and five minutes were 2 and 3, respectively. The infant was resuscitated by endotracheal intubation, manual bag ventilation with 1.0 fraction of inspired oxygen (Fio_2), and administration of sodium bicarbonate, epinephrine, and 5% plasma protein fraction (human) through the umbilical arterial catheter. An initial blood sample showed a Pao_2 of 32 mm Hg, a $Paco_2$ of 50 mm Hg, and a pH of 7.23. On transfer to the intensive care unit at 1½ hours of age, treatment with a pneumatically operated, time-cycled pressure ventilator was begun, using a peak inspiratory pressure of 25 cm H_2O, positive end-expiratory pressure of cm H_2O, at a rate of 30 per minute, Fio_2 of 1.0, and an inspiratory-expiratory ratio of 1:2. The Pao_2 was now 62 mm Hg; the $Paco_2$, 54 mm Hg; the pH, 7.18; and the base deficit, −9.2 mEq/L.

Initial chest roentgenogram showed bilateral coarse granular pattern and diffuse aeration disturbance bilaterally. The patient's clinical condition remained poor despite supportive therapy, and a blood sample taken at three hours after admission revealed a Pao_2 of 39 mm Hg, a $Paco_2$ of 131 mm Hg, a pH of 7.46, and a base excess of +9.2 mEq/L. The peak inspiratory pressure was gradually increased to 34 cm H_2O while the other respirator settings remained the same.

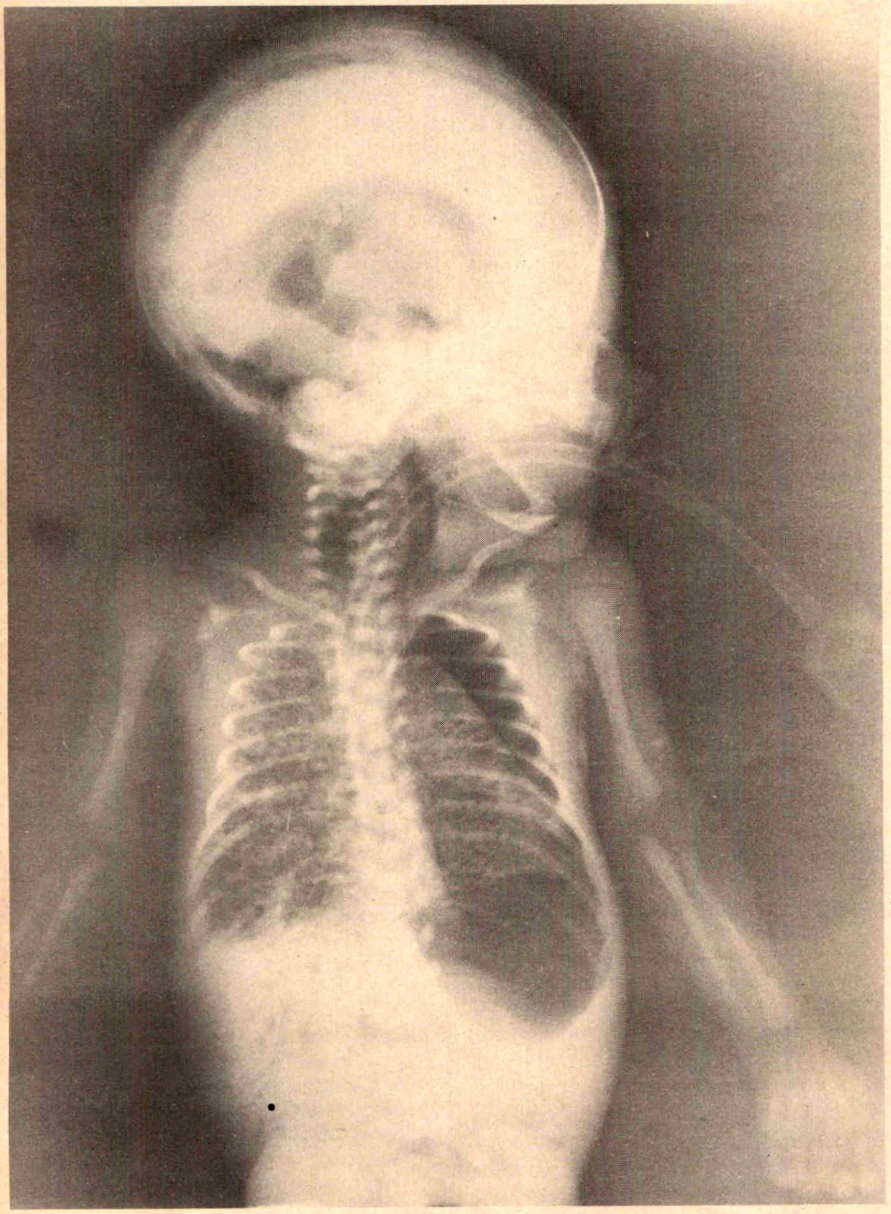
A repeated chest roentgenogram showed some improvement in the aeration of both lungs but no evidence of pneumothorax. Ten hours after admission, the heart rate dropped to 20 beats per minute. Cardiopulmonary resuscitation was immediately instituted. Substantial amounts of air in the form of bubbly, dark blood were noted on aspiration of the umbilical arterial line prior to giving sodium bicarbonate and epinephrine. An umbilical venous catheter was immediately inserted and the medications were given through this route. Very bubbly, dark blood was also noted from the umbilical venous line. Transillumination of the chest using a mini-light portable illuminator with a flexible optic light probe showed a left-sided pneumothorax. Sixty milliliters of air was obtained from the left pleural cavity by needle aspiration. The heart stopped beating and further efforts to resuscitate the infant were unsuccessful. A whole body roentgenogram taken ten minutes postmortem revealed pulmonary interstitial emphysema bilaterally and a tension pneumothorax on the left side as shown in the Figure. There was air in the hepatic veins, inferior vena cava, and in the vasculature of the neck. A considerable collection of air in the superior sagittal

sinus, cisterna magna, and lateral ventricles of the brain was also noted.

Autopsy Findings.—On autopsy, the combined weight of the lungs was 26.7 g. They were atelectatic, and crepitance was noted on the surface. Microscopic examination showed few alveoli lined by hyaline membrane. The alveolar airways were small and the lungs consisted preponderantly of interstitial tissue and alveolar pneumatocytes. The brain weighed 60 g, and it was normal in appearance on gross examination. Microscopic examination of the brain was unremarkable.

Comment.—Gas in the fetal skull as a sign of intrauterine death was described by Northway and Walls.[6] Henderson-Smart[7] reported a case of massive air embolism that included the presence of air in the cerebral venous sinuses of an infant that was detected by routine postmortem roentgenogram. Quisling et al,[8] in a series of postmortem roentgenograms obtained on 22 premature infants, were able to demonstrate progressive and spontaneous intracranial gas accumulation. In one case they noted the accumulation of gas in the subarachnoid and intraventricular spaces one hour after death. In another case this spontaneous accumulation of gas in the intracerebral veins and sinuses was not noted until four hours after death.

In our patient, the presence of intracranial gas was probably due to a massive embolic phenomenon rather than that of a spontaneous postmortem accumulation of gas. Unlike most routine postmortem roentgenograms, this infant's whole body roentgenogram demonstrating massive intravascular and intracranial gas was taken immediately after death. Also, clinical evidence of intravascular air embolism was noted by aspiration of foamy blood from the arterial and the venous catheter. Massive formation of extraventilatory air[3] with possible embolization into the brain should be suspected when air bubbles are noted in the blood from the umbilical vessel catheter, provided all tubings and connections have been checked and found to be intact. Gas in the veins of the head and in the sinuses of the dura mater could escape into the adjacent subarachnoid space thus leading to intracranial accumulation of air. Intracranial air embolism, an unusual and catastrophic complication, will probably be observed with increasing frequency with the widespread use of ventilatory assistance in the very premature neonates.



Whole body roentgenogram taken ten minutes postmortem showing considerable collection of air in the superior sagittal sinus, cisterna magna, lateral ventricles, vascular structure of the neck, left pleural cavity, hepatic veins, and inferior vena cava.

Antibiotic-Resistant Streptococci

Sir.—In a recent issue of the JOURNAL (133:1143-1145, 1979), Maruyama et al reported a high percent of group A streptococci in Japan to be resistant to erythromycin and other antibiotics during a one-year survey (1974-1975). They concluded that widespread resistance might be related to excessive use of erythromycin in streptococcal therapy. We have also encountered erythromycin-resistant streptococci at our institution.

Report of a Case.—A 5-year-old boy with a sore throat was given oral penicillin V, 250 mg four times daily for ten days, after isolation of group A β-hemolytic streptococcus on culture of throat material (sheep-blood agar with bacitracin disk for presumptive group A identification). Symptoms abated within six days. Follow-up throat cultures at 13 and 20 days after the original diagnosis were still positive for group A β-hemolytic streptococcus, and therapy with penicillin was continued for a total of 27 days. A culture at 31 days was also positive, but the patient was asymptomatic (suggesting a carrier state[1]) and therapy with antibiotics was discontinued. A second culture was done at 33 days. Bacterial sensitivities (by Kirby-Bauer method[2]) showed the organism to be erythromycin-resistant, but sensitive to penicillin, oxacillin, cephalothin sodium, ampicillin sodium, and tetracycline.

Comment.—Erythromycin had not been used in this patient, either during these streptococcus-positive weeks or previously. In the eight weeks since the isolation of streptococcus from this patient, our laboratory performed susceptibility tests on 100 positive pharyngeal cultures from our clinic. Of 100 isolates, 22 were erythromycin-resistant; all were penicillin-sensitive.

Erythromycin-resistant streptococci have been reported in the United States previously.[3,4] However, in view of the experience in Japan and in view of the frequent use made of this antibiotic as a second-line drug in the treatment of streptococcal pharyngitis (and its acceptance by the American Heart Association for prevention of rheumatic fever), clinicians need to know whether or not the drug they prescribe will be effective. We should monitor the antibiotic susceptibility of cultured streptococci and perform follow-up throat cultures.

Crouzon's Disease Data

Sir.—I read with great interest the article by Powazek and Billmeier entitled "Assessment of Intellectual Development after Surgery for Craniofacial Disorders" (JOURNAL 133:151-153, 1979).

I have seen a number of cases of Crouzon's disease, including some with results that are similar to those the authors noted in their case report. There are, as the authors point out, a number of substantive variables that they have not measured. One variable, which in many ways may be one of the more important, is the hearing acuity of the affected patients and what interventions, either medical, surgical, or rehabilitative, may have been performed to optimize the hearing of each patient. It would be most important, if the authors have this data, if this could be made available.

Infantile Cholestatic Liver Disease

Sir.—We read with interest the report by Rosenthal et al (JOURNAL 133:1195-1196, 1979) concerning infantile cholestatic liver disease associated with alpha$_1$-antitrypsin deficiency and the Pi-SZ phenotype. We have seen a similar patient who at 1 month of age had failure to thrive and conjugated hyperbilirubinemia. The only other clinical abnormality was a cholesterol level of 415 mg/dL. Rose bengal sodium I 131 did not enter the intestine.

An operative cholangiogram and open biopsy were performed before the results of the alpha$_1$-antitrypsin estimation were known. Bile ducts were present, but some observers thought they were small. Histologically, there was some increase in hepatic ducts and mononuclear infiltration. Diastase-resistant, PAS-positive granules were seen in both hepatocytes and Kupffer's cells. The alpha$_1$-antitrypsin level was estimated to be 90 mg/dL by radial immunodiffusion. The infant's Pi type was SZ, the father's SS, and the mother's MZ. By 2 months of age, the total bilirubin level was 3.3 mg, with the direct at 0.1 mg/dL, and the cholesterol was 292. At 5 months of age he was growing well and the cholesterol level had fallen to 164 mg/dL.

We had been concerned with the specificity of the histological examination of the liver biopsy specimen using PAS and diastase. Sections from a number of patients with jaundice, including galactosemia, unexplained fibrosis, hepatic ductular hypoplasia, and neonatal hyperbilirubi-

nemia were prepared and stained in the same way. All of these patients had normal or elevated levels of alpha$_1$-antitrypsin. We could not detect any difference in the appearance of the PAS-positive granules between any of these samples and that from the infant with the SZ phenotype. We noticed that in published, later biopsy material, the granules are larger and there are clear halos around them. We wonder if other investigators have been similarly confused, particularly in light of the recent report of similar granules in a family with the Dubin-Johnson syndrome.[1]

1. Lo NS, Chan CW, Hutchison JH: Dubin-Johnson syndrome with some unusual features in a Chinese family. *Arch Dis Child* 54:529-533, 1979.

In Reply.—We are gratified that Drs Harris and Beatty have seen a case that resembles the one reported by us. It was our intent to point out that PAS-positive, diastase-resistant granules may be observed during the first two months in periportal hepatocytes and in Kupffer cells of patients heterozygous for alpha-1-antitrypsin deficiency. As indicated in our article, examination with the electron microscope demonstrated that these deposits were located in the rough endoplasmic reticulum of hepatocytes. In contrast, in patients with cholestasis due to other causes, PAS-positive, diastase-resistant granules may be seen in damaged hepatocytes not usually confined to peripheral regions of lobules, and concentrated in lysosomes rather than in expanded regions of the rough endoplasmic reticulum. The deposits of lipofuscin-melanin pigment observed in Dubin-Johnson syndrome, to which Drs Harris and Beatty refer, are panlobular in distribution and have a dark brown color that may be readily distinguished from the deep red or purple displayed by alpha-1-antitrypsin deposits. Although we are in agreement with Drs Harris and Beatty that the finding of PAS-positive, diastase-resistant granules in hepatocytes is not pathognomonic for alpha-1-antitrypsin deficiency, their presence in a young infant with cholestasis is strongly suggestive, and warrants assessment by determination of serum alpha-1-antitrypsin activity and Pi phenotyping.

Isosexual Precocity

Sir.—Hung et al in a recent issue of the JOURNAL (134:25-27, 1980) advocated that a computerized tomography (CT) scan be done on any girl or boy with isosexual precocity without an obvious cause or in whom a CNS disorder is suspected. Root has reported that 85% of the cases of isosexual precocity in girls are idiopathic.[1] Eberlein et al studied a series of 86 girls with sexual precocity, and found no cases due to a neurologic disorder.[2] At Charlotte (NC) Memorial Hospital and Medical Center we have seen 77 girls with isosexual precocious development from 1974 through 1979. Only two of these girls had organic pathology—one with an ovarian cyst and one with hydrocephalus (Table). In the cases reported by Hung et al, one girl had hydrocephalus and another had seizures associated with sexual precocity. In both instances, a CT scan was indicated on neurologic considerations alone.

In boys, the incidence of serious pathology is much higher (Table). Root notes that in boys, only 66% of all cases of sexual precocity are idiopathic.[1] The boy in Hung's case had pubertal-sized testes, indicating a central or CNS origin for the precocity. In boys with prepubertal testes and precocity, an adrenal gland disorder would be more common.

Isosexual Precocious Puberty, 1974-1979

	No.
Girls	
Idiopathic	36
Premature thelarche	24
Premature pubarche	15
CNS (hydrocephalus)	1
McCune-Albright disease (ovarian cyst)	1
Boys	
Premature pubarche	6
Adrenogenital syndrome	4
Idiopathic	2
CNS disorder	1

The cost of a CT scan in our institution is $245. The radiation from this procedure is 2 to 10 rads.[3] Although a CT scan may be indicated in selected instances of precocious puberty in girls when a CNS cause is suspected from history or physical examination, we do not think it should be a routine procedure.

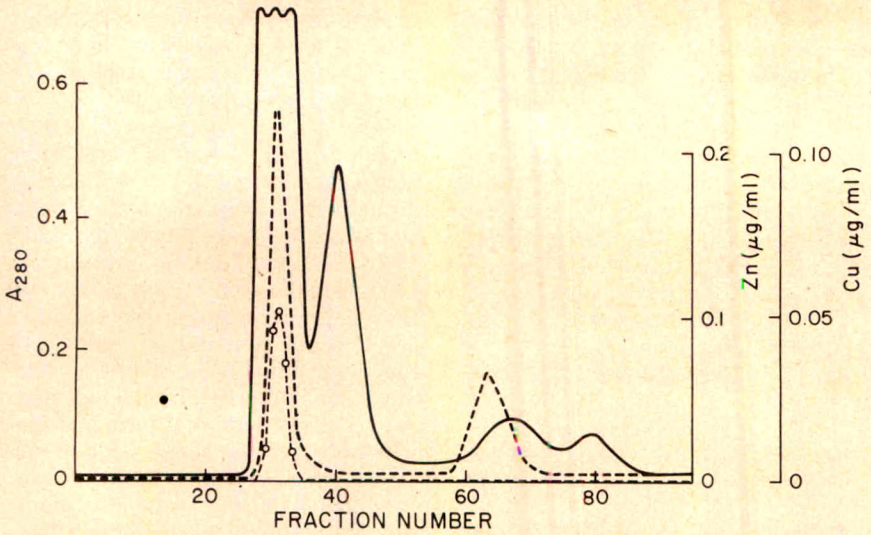
Copper Ligands in Human Milk: A Vehicle for Copper Supplementation in the Treatment of Menkes' Disease?

To the Editor.—Recent results from our laboratory have shown that human milk, unlike cow's milk, contains a low-molecular-weight (LMW) zinc complex,[1] now identified as zinc citrate.[2] We have therefore hypothesized that the therapeutic value of human milk in the treatment of acrodermatitis enteropathica (AE), a genetic disorder of zinc metabolism, is due to the presence of this complex, which is thought to be highly available for absorption.[3,4]

Assuming that human milk may contain LMW copper as well as zinc complexes, Williams et al[5] have suggested that human milk may also be of therapeutic value in the treatment of Menkes' kinky hair disease, a sex-linked genetic disorder in humans that is manifested by abnormal intestinal copper absorption and many characteristics similar to those of copper-deficient animals.[6] Despite the aggressive use of copper in infants with Menkes' disease, the prognosis for these patients has not improved.[7] Danks et al[8] have proposed that the primary biochemical lesion in Menkes' disease is the presence of an abnormal protein with a high avidity for copper



Gel filtration of skimmed human milk (2 mL) on a 1.6 × 100-cm fractionating column (Sephadex G-50) in 0.1M ammonium acetate buffer (pH, 6.5). Solid line indicates protein (A_{280}); circles, copper; and broken line, zinc.

and have suggested that treatment of the disease may necessitate the use of a copper chelate which can bypass the mutant protein, making copper available to the cell in concentrations commensurate with both normal cell function and viability. According to the hypothesis of Williams et al,[5] a LMW copper complex (analogous to that found for zinc) that bypasses the intestinal block in Menkes' disease might be found in human milk. These investigators therefore evaluated human milk therapy, but it was not effective. However, we have been studying the molecular localization of copper as well as zinc in human milk and now report that it contains no LMW copper complex.

Methods.—Human milk was obtained from healthy donors through the Mother's Milk Unit, San Jose, Calif. Milk samples were defatted by centrifugation at 10,000 g for 30 minutes. Defatted milk samples were subjected to gel filtration on a (Sephadex G-50) 1.6 × 100-cm fractionating column in 0.1M ammonium acetate buffer at pH 6.5. The gel was treated in sodium borohydride to eliminate small amounts of charges causing nonspecific absorption to the gel matrix.[9] Under these conditions, recovery of copper from the column was 95% to 100%. Absorbance at 280 nm was recorded spectrophotometrically, and copper and zinc in collected fractions as well as in samples were analyzed by flame atomic absorption spectrophotometry.

Results.—The elution profile for human milk on Sephadex G-50 can be seen in the Figure. Copper elutes in a single peak at the elution volume of the column that corresponds to a molecular weight of more than 30,000. No LMW copper complex could be detected. In contrast, zinc elutes in two peaks, one a high molecular weight peak and the second a LMW peak (less than 2,000). Milk samples collected at varying times postpartum showed very similar relative distribution of copper and zinc, and in no case was any LMW copper complex observed.

Comment.—These results demonstrate that in contrast to zinc[2] and iron,[10] there are no LMW copper complexes found in human milk. The lack of such a LMW copper complex may perhaps explain, at least in part, the failure of copper supplementation by milk as a therapeutic treatment for Menkes' disease. These results also provide evidence that the genetic disorders AE and Menkes' disease, although both characterized by abnormal metabolism of a trace element, do not, most likely, produce their effects by similar mechanisms. Thus, while AE can be treated successfully postnatally, it is possible that Menkes' disease requires prenatal treatment. The use of prenatal nutritional manipulation for the prevention or amelioration of deleterious effects of mutant genes has been demonstrated in animal models in the mutant mouse *crinkled*,[11,12] in which there is a disorder of copper metabolism, and in the mutant mouse *pallid*, which has a disorder of manganese metabolism.[13] Likewise, the *screwneck* manifestation in *pastel* mink is prevented by prenatal manganese supplementation.[14] In all three of these cases, only prenatal, and not postnatal, treatment was effective.

Books

Diseases of the Small Intestine in Childhood, ed 2, by J. Walker-Smith, 412 pp, $49.50, Baltimore, University Park Press, 1979.

This is the second edition of a book first published in 1975. Although the format remains exactly the same, there has been extensive revision of some of the chapters. The author states in the preface that in the four years since his first edition there has been a remarkable expansion of knowledge about diseases of the small intestine. As a consequence, he has felt a need for a new edition to take into account these recent developments. He has succeeded admirably in achieving this goal.

The book contains 12 chapters, which can be divided into three general areas. First is a general introduction, which includes a discussion of history, physical examination, and investigative techniques. The middle section concerns itself with specific diseases, which include coeliac disease, protein intolerance, gastroenteritis, sugar malabsorption, parasites, and Crohn's disease. Finally, there are two chapters on surgical disease of the small bowel. The two areas that have been greatly expanded include the discussions on gastrointestinal viruses and immunology of the gut.

Several chapters are outstanding. Dr Walker-Smith's discussion of small bowel morphology is as well done as any I have seen, but the highlight of the book is the chapter on coeliac disease and dietary protein intolerance. Dr Walker-Smith has a vast clinical experience in these areas, which he beautifully couples to an extensive literature review. The combination results in an unparalleled discussion of the topics. The entire book is well referenced, as evidenced by a 40-page bibliography.

Unfortunately, several weaknesses do exist. The introductory chapter was poorly balanced, with too much space devoted to immunology and not enough to normal intestinal physiology. The chapter on history and physical examination was very superficial and could well have been left out. I also found the chapters on Crohn's disease and massive small-bowel resection rather weak, particularly in the area of management.

These few weaknesses do not come close to offsetting the strengths of the book. Therefore, I recommend this book without reservation for anyone interested in diseases of the small intestine in children.

Pediatric Neuromuscular Diseases, by Kenneth F. Swaiman and Francis S. Wright, 283 pp, 106 illus, $39.50, St Louis, CV Mosby Co, 1979.

Pediatric Neuromuscular Disease is intended to present a systematic approach to the child with neuromuscular disorders. The first chapter reviews neuromuscular anatomy, history taking and physical examination, normal maturation of the motor system, and central and peripheral hypotonias. The second chapter reviews embryonic development and ultrastructure of muscles and the diagnostic usefulness of electromyography, nerve-conduction studies, and muscle biopsy. Next, the pediatric neuromuscular diseases are classified according to the anatomic location of their chief pathologic conditions. Single chapters are allotted to motor neuron disease, disorders of nerve roots and peripheral nerves, and diseases of the neuromuscular junction. The final three chapters are devoted to muscle disease, discussed under the categories of progressive muscular dystrophies, unusual myopathies and congenital defects of muscle, and myositis.

The detailed clinical descriptions and discussions of differential diagnosis make this a helpful book for the student or clinician in pediatric neuromuscular disease. The more recently described congenital myopathies and metabolic diseases are included, as well as some categories, such as traumatic and vascular neuropathies, that are often omitted from similar texts. The sections on the initial clinical observations and the treatment of Duchenne's muscular dystrophy and of myasthenia gravis are particularly comprehensive and detailed. Good-quality illustrations, including electron micrographs, contribute to the text. Several helpful tables present the differentiating features of the individual disorders within a group of diseases, such as the degenerative anterior horn cell diseases, the neuropathies, the glycogen storage diseases, and periodic paralyses.

Several problems, however, detract from the usefulness of this book as an aid to approaching the child with neuromuscular disease. First, the discussions of pathophysiology of some entities are incomplete. For instance, the discussion of botulism fails to mention the effect of the toxin on release of acetylcholine from nerve terminals. In the description of myotonic dystrophy, no differentiation is made between the congenital form and that with onset in later childhood, and consideration of an intrauterine/maternal factor in the pathogenesis of the congenital form is completely omitted.

Second, organization within the chapters is difficult to follow. This is due in part to the order chosen for presentation of various topics within a chapter. For instance, in chapter 3, benign congenital hypotonia is presented in the middle of the section on degenerative conditions—a misleading representation of its very different prognosis. The unclear chapter organization is also related to the confusing progression of type face chosen to delineate topics and subtopics within the chapters. Subheadings under each disease are in much bolder face than is the disease heading itself. Also, there are inconsistencies in type used for similar headings. For instance, the boldest type to appear in the book is first used to delineate a short section on infectious diseases that cause anterior horn cell disease. Inclusion of the division headings in the "Table of Contents" and at the beginning of each chapter would have been helpful.

Finally, many sections, particularly in the first three chapters, do not read with ease, largely due to redundancy and poor paragraph organization.

Despite these problems, the book's inclusiveness, its up-to-date references, and its detailed clinical descriptions make it a helpful source for students or clinicians caring for children who have neuromuscular disease. For the full-time myologist, it is less helpful than other texts currently available.

PAIN GONE

while the antibiotic gets going

An effective adjuvant to systemic antibiotic treatment, AURALGAN promptly relieves the pain and reduces the inflammation of acute otitis media, while the antibiotic of choice fights the infection.

AURALGAN contains the topical analgesic action of benzocaine and antipyrine plus glycerin dehydrated...a decongestant so hygroscopic that it "blots up" excess moisture through the tympanic membrane, for relief of pressure and pain in the middle ear.

BRIEF SUMMARY
(For full prescribing information, see package circular.)
AURALGAN® Otic Solution
Each ml contains:

Antipyrine	54.0 mg
Benzocaine	14.0 mg
Glycerin dehydrated q.s. to	1.0 ml

(contains not more than 1.0% moisture) (also contains oxyquinoline sulfate)
INDICATIONS: *Acute otitis media of various etiologies*
—prompt relief of pain and reduction of inflammation in the congestive and serous stages
—adjuvant therapy during systemic antibiotic administration for resolution of the infection
CONTRAINDICATIONS: Hypersensitivity to any of the components or substances related to them./In the presence of spontaneous perforation or discharge.
DOSAGE AND ADMINISTRATION: *Acute otitis media:* Instill AURALGAN, permitting the solution to run along the wall of the canal until it is filled. Avoid touching the ear with dropper. Then moisten a cotton pledget with AURALGAN and insert into meatus. Repeat every one to two hours until pain and congestion are relieved.
HOW SUPPLIED: No.1000—AURALGAN® Otic Solution, in package containing 15 ml (½ fl oz) bottle with separate dropper-screw cap attachment.

...in acute otitis media

Auralgan®

OTIC SOLUTION

FULLY COMPATIBLE WITH SYSTEMIC ANTIBACTERIAL THERAPY. ON PRESCRIPTION ONLY.

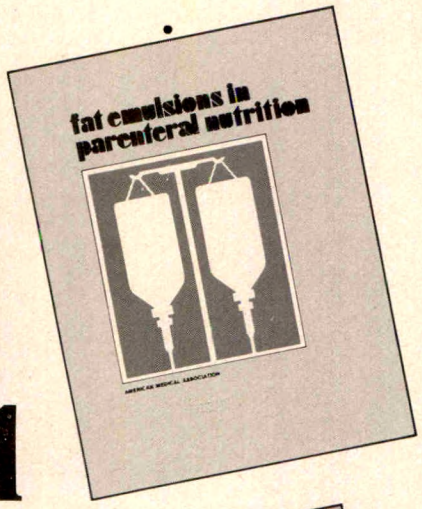
From the AMA...
3 ways to update yourself on the latest advances in clinical nutrition!

Newer ways of providing nourishment have improved the prognosis for many patients, particularly the critically ill. Nutritional rehabilitation can significantly enhance the effectiveness of surgical, pharmacological, and radiological therapy.

These three publications from the American Medical Association relate advances in nutrition to the improved care of patients. They are must reading for the physician who wants to keep current on the new developments in this important new area of medicine.

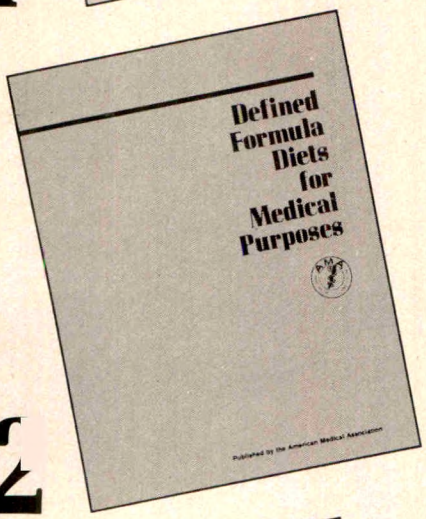
1



Fat Emulsions in Parenteral Nutrition, edited by H.C. Meng, M.D., Ph.D. and Douglas W. Wilmore, M.D.

A presentation of experimental and clinical studies on the intravenous use of fat emulsions. Divided into three sections, the book covers the metabolism of fatty acids and functions of essential fatty acids (EFA), with information on EFA deficiency; lipids as sources of energy and EFA; and pathophysiology related to the use of fat emulsions, with discussion of side effects and interrelations with other nutrients.

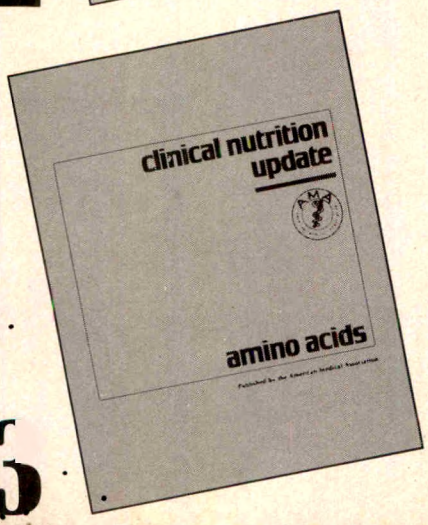
2



Defined Formula Diets for Medical Purposes, edited by Maurice E. Shils, M.D., Sc.D.

A discussion of newer developments in oral feeding with chemically defined liquid diets. The first half of the book describes the development and formulation of defined formula diets, as well as the physiologic and metabolic effects of these nutrient solutions. Other sections present clinical experiences with defined formula diets in nutritional rehabilitation, pediatric care, management of catabolic states, and treatment of diseases such as inflammatory bowel disease, renal failure and acute pancreatitis.

3



Clinical Nutrition Update: Amino Acids, edited by Harry L. Green, M.D., Malcolm A. Holliday, M.D. and Hamish N. Munro, D.Sc., M.B.

A review of advances in the understanding of amino acid requirements and metabolism and the application of this knowledge to management of illness. The book includes reports on the use of oral and intravenous amino acid preparations in treating uremia, liver failure, sepsis, trauma, abnormal amino acid metabolism, premature infants, etc. Factors influencing tissue uptake of amino acids and the synthesis of protein are also discussed, along with the methods of evaluating protein homeostasis and regulating the amino acid supply.

Advertising Principles: Each advertisement in this issue has been reviewed and complies with the principles governing advertising in AMA scientific publications. A copy of these principles is available on request.

Subscription Rates: The yearly rates for the AMERICAN JOURNAL OF DISEASES OF CHILDREN is as follows: for members of the AMA, $1.50, included in the annual membership dues; for non-members, $24 for one year, $40 for two years in the United States and US possessions; all other countries, $34 for one year, $60 for two years. Special yearly price to residents, interns, and medical students in the United States and US possessions, one year, $12; two years, $20. Address all subscription communications to Circulation-Fulfillment Department. Phone: 312, 751-6079.

Change of Address: POSTMASTER, send address changes to Helen R. Mazur, Director, Circulation-Fulfillment. Notification of address changes should be sent at least six weeks in advance, including both old and new address, and a mailing label taken from the most recent copy. Include your new zip code number.

AMERICAN JOURNAL OF DISEASES OF CHILDREN (ISSN 0002-922X) is published monthly by the American Medical Association, 535 N Dearborn St, Chicago, IL 60610, and is an official publication of the Association. Second-class postage paid at Chicago and at additional mailing office.

a chance for a better life with Depakene®
Valproic Acid

For your patients with mixed seizures including absence, or pure absence

Effective seizure control[1] without cosmetic disfigurement

In 28 studies of patients with mixed grand mal and absence, 76% of all patients gained significant improvement; over one-third became seizure-free. In 60 studies involving pure absence, 86% of patients were improved; half became seizure-free.

While serious side effects, including fatal hepatitis, have occurred, the most common side effect with Depakene is G.I. upset, which usually responds to temporary dosage reduction. Problem sedation is not common and cosmetic stigmata such as gum hypertrophy and hirsutism do not occur.

A widely useful anticonvulsant

Depakene is indicated as sole or adjunctive therapy in both simple and complex absence seizures. It is also indicated for adjunctive treatment of patients with multiple seizure types which include absence. Clinical response has been especially noteworthy among patients with generalized tonic-clonic attacks, or with minor motor seizures (e.g., myoclonic movements, akinetic seizures), where combined with absence.

Offering your patients a chance for a better life

Sustained freedom from seizures can mean a drivers license, an active social schedule, involvement in athletic competition—a better life for your patient.

1. Worldwide studies of Depakene experience (Data refer only to grand mal and/or absence seizures. Since each type was evaluated separately, some patients appear in both groups. Though most of these studies were uncontrolled and had widely differing protocols, their collective data clearly support efficacy of the drug).

See overleaf for prescribing information

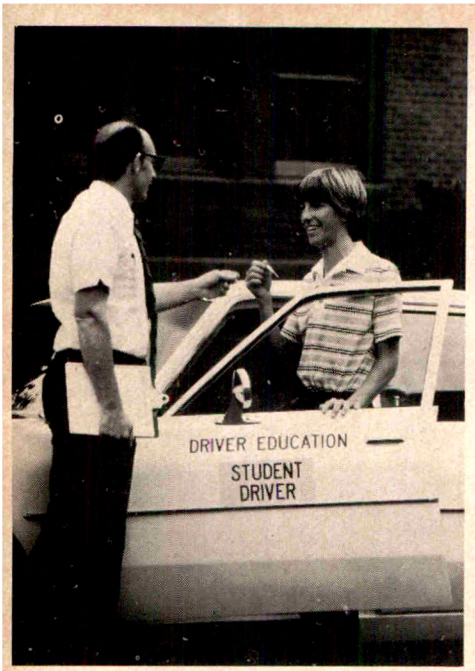
Depakene®
Valproic Acid Capsules 250 mg
250 mg/5 ml syrup



Depakene®
Valproic Acid

Offering a chance for a better life for your patients with mixed seizures including absence, or pure absence

PRESCRIBING INFORMATION

INDICATIONS: DEPAKENE (valproic acid) is indicated for use as sole and adjunctive therapy in the treatment of simple and complex absence seizures, including petit mal. DEPAKENE may also be used adjunctively in patients with multiple seizure types which include absence seizures.

In accordance with the International Classification of Seizures, simple absence is defined as very brief clouding of the sensorium or loss of consciousness (lasting usually 2-15 seconds), accompanied by certain generalized epileptic discharges without other detectable clinical signs. Complex absence is the term used when other signs are also present.

CONTRAINDICATIONS: DEPAKENE (valproic acid) is contraindicated in patients with known hypersensitivity to the drug.

WARNINGS: Hepatic failure resulting in fatalities has occurred in patients receiving DEPAKENE. These incidences usually have occurred during the first six months of treatment with DEPAKENE. Liver function tests should be performed prior to therapy and at frequent intervals thereafter. Caution should be observed when administering DEPAKENE to patients with pre-existing hepatic disease.

The drug should be discontinued immediately in the presence of significant hepatic dysfunction, suspected or apparent. The frequency of adverse effects (particularly elevated liver enzymes) may increase with increasing dose. Therefore, the benefit gained by increased seizure control by increasing the dosage must be weighed against the increased incidence of adverse effects sometimes seen at higher dosages.

Usage in Pregnancy: THE EFFECTS OF DEPAKENE IN HUMAN PREGNANCY ARE UNKNOWN. ANIMAL STUDIES HAVE DEMONSTRATED TERATOGENICITY.

Studies in rats demonstrated placental transfer of the drug. Doses greater than 65 mg/kg/day given to pregnant rats and mice produced skeletal abnormalities in the offspring, primarily involving ribs and vertebrae; doses greater than 150 mg/kg/day given to pregnant rabbits produced fetal resorptions and (primarily) soft-tissue abnormalities in the offspring. In rats a dose-related delay in the onset of parturition was noted. Postnatal growth and survival of the progeny were adversely affected, particularly when drug administration spanned the entire gestation and early lactation period.

THERE ARE MULTIPLE REPORTS IN THE CLINICAL LITERATURE WHICH INDICATE THAT THE USE OF ANTICONVULSANT DRUGS DURING PREGNANCY RESULTS IN AN INCREASED INCIDENCE OF BIRTH DEFECTS IN THE OFFSPRING. ALTHOUGH DATA ARE MORE EXTENSIVE WITH RESPECT TO TRIMETHADIONE, PARAMETHADIONE, PHENYTOIN, AND PHENOBARBITAL, REPORTS INDICATE A POSSIBLE SIMILAR ASSOCIATION WITH THE USE OF OTHER ANTICONVULSANT DRUGS. THEREFORE, ANTICONVULSANT DRUGS SHOULD BE ADMINISTERED TO WOMEN OF CHILDBEARING POTENTIAL ONLY IF THEY ARE CLEARLY SHOWN TO BE ESSENTIAL IN THE MANAGEMENT OF THEIR SEIZURES.

Anticonvulsant drugs should not be discontinued in patients in whom the drug is administered to prevent major seizures because of the strong possibility of precipitating status epilepticus with attendant hypoxia and threat to life. In individual cases where the severity and frequency of the seizure disorder are such that the removal of medication does not pose a serious threat to the patient, discontinuation of the drug may be considered prior to and during pregnancy, although it cannot be said with any confidence that even minor seizures do not pose some hazard to the developing embryo or fetus.

The prescribing physician will wish to weigh these considerations in treating or counseling epileptic women of childbearing potential.

PRECAUTIONS: *Hepatic dysfunction:* See WARNINGS.

General: Because of reports of thrombocytopenia and platelet aggregation dysfunction, platelet counts and bleeding time determination are recommended before initiating therapy and at periodic intervals. It is recommended that patients receiving DEPAKENE be monitored for platelet count prior to planned surgery. Clinical evidence of hemorrhage, bruising or a disorder of hemostasis/coagulation is an indication for reduction of DEPAKENE dosage or withdrawal of therapy pending investigation.

Since DEPAKENE (valproic acid) may interact with concurrently administered anticonvulsant drugs, periodic serum level determinations of concomitant anticonvulsant drugs are recommended during the early course of therapy. (See Drug Interactions).

DEPAKENE is partially eliminated in the urine as a keto-metabolite which may lead to a false interpretation of the urine ketone test.

Information For Patients: Since DEPAKENE may produce CNS depression, especially when combined with another CNS depressant (e.g., alcohol), patients should be advised not to engage in hazardous occupations, such as driving an automobile or operating dangerous machinery, until it is known that they do not become drowsy from the drug.

Drug Interactions: DEPAKENE may potentiate the CNS depressant activity of alcohol.

THERE IS EVIDENCE THAT DEPAKENE MAY CAUSE AN INCREASE IN SERUM PHENOBARBITAL LEVELS, ALTHOUGH THE MECHANISM OF THE INTERACTION IS UNKNOWN. ALL PATIENTS RECEIVING CONCOMITANT BARBITURATE THERAPY SHOULD BE CLOSELY MONITORED FOR NEUROLOGICAL TOXICITY, SERUM BARBITURATE DRUG LEVELS OBTAINED, IF POSSIBLE, AND THE BARBITURATE DOSAGE DECREASED, IF APPROPRIATE.

Primidone is metabolized into a barbiturate and, therefore, may also be involved in a similar or identical interaction.

THERE IS CONFLICTING EVIDENCE REGARDING THE INTERACTION OF DEPAKENE WITH PHENYTOIN. IT IS NOT KNOWN IF THERE IS A CHANGE IN UNBOUND (FREE) PHENYTOIN SERUM CONCENTRATIONS. THE DOSAGE OF PHENYTOIN SHOULD BE ADJUSTED AS REQUIRED BY THE CLINICAL SITUATION.

THE CONCOMITANT USE OF VALPROIC ACID AND CLONAZEPAM MAY PRODUCE ABSENCE STATUS.

Caution is recommended when DEPAKENE (valproic acid) is administered with drugs affecting coagulation, e.g., aspirin and warfarin. (See ADVERSE REACTIONS).

Carcinogenesis, Mutagenesis: There has been insufficient study of the drug in animals to determine whether it has carcinogenic potential. Carcinogenicity studies in rats and mice are currently in progress.

Mutagenesis studies on DEPAKENE have been performed using bacterial and mammalian systems. These studies have provided no evidence of a mutagenic potential for DEPAKENE.

Pregnancy: See WARNINGS.

Nursing Mothers: DEPAKENE is excreted in breast milk. It is not known what effect this would have on a nursing infant. As a general rule, nursing should not be undertaken while a patient is receiving DEPAKENE.

Fertility: Chronic toxicity studies in juvenile and adult rats and dogs demonstrated reduced spermatogenesis and testicular atrophy at doses greater than 200 mg/kg/day in rats and greater than 90 mg/kg/day in dogs. Segment I fertility studies in rats have shown doses up to 350 mg/kg/day for 60 days to have no effect on fertility. THE EFFECT OF DEPAKENE (VALPROIC ACID) ON THE DEVELOPMENT OF THE TESTES AND ON SPERM PRODUCTION AND FERTILITY IN HUMANS IS UNKNOWN.

ADVERSE REACTIONS: Since DEPAKENE (valproic acid) has usually been used with other anticonvulsant drugs, it is not possible, in most cases, to determine whether the following adverse reactions can be ascribed to DEPAKENE alone, or the combination of drugs.

Gastrointestinal: The most commonly reported side effects at the initiation of therapy are nausea, vomiting and indigestion. These effects are usually transient and rarely require discontinuation of therapy. Diarrhea, abdominal cramps and constipation have been reported. Both anorexia with some weight loss and increased appetite with weight gain have also been reported.

CNS Effects: Sedative effects have been noted in patients receiving valproic acid alone but are found most often in patients receiving combination therapy. Sedation usually disappears upon reduction of other anticonvulsant medication. Ataxia, headache, nystagmus, diplopia, asterixis, "spots before eyes", tremor, dysarthria, dizziness, and incoordination have rarely been noted. Rare cases of coma have been noted in patients also on phenobarbital.

Dermatologic: Transient increases in hair loss have been observed. Skin rash and petechiae have rarely been noted.

Psychiatric: Emotional upset, depression, psychosis, aggression, hyperactivity and behavioral deterioration have been reported.

Musculoskeletal: Weakness has been reported.

Hematopoietic: Thrombocytopenia has been reported. Valproic acid inhibits the secondary phase of platelet aggregation. (See DRUG INTERACTIONS). This may be reflected in altered bleeding time. Bruising, hematoma formation and frank hemorrhage have been reported. Relative lymphocytosis and hypofibrinogenemia have been noted. Leukopenia and eosinophilia have also been reported.

Hepatic: Increases in serum alkaline phosphatase and elevations of serum glutamic oxaloacetic transaminase (SGOT) have been noted. Elevation of SGOT may be dose related. Elevations of SGPT and LDH have been noted less frequently. Isolated cases of severe hepatotoxicity have been reported but do not appear dose related. (See WARNINGS).

OVERDOSAGE: A single case of overdosage with valproic acid has been reported. After ingesting 36 grams in combination with phenobarbital and phenytoin, the patient presented in deep coma. An electroencephalogram recorded diffuse slowing, compatible with the state of consciousness. The patient made an uneventful recovery.

Since DEPAKENE is absorbed very rapidly, gastric lavage may be of limited value. General supportive measures should be applied with particular attention being given to the maintenance of adequate urinary output.

DOSAGE AND ADMINISTRATION: DEPAKENE (valproic acid) is administered orally. The recommended initial dose is 15 mg/kg/day, increasing at one week intervals by 5 to 10 mg/kg/day, until seizures are controlled or side effects preclude further increases. The maximum recommended dosage is 60 mg/kg/day. If the total daily dose exceeds 250 mg, it should be given in a divided regimen.

The frequency of adverse effects (particularly elevated liver enzymes) may increase with increasing dose. Therefore, the benefit gained by increased seizure control by increasing dosage must be weighed against the increased incidence of adverse effects sometimes seen at higher doses.

The following table is a guide for the initial daily dose of DEPAKENE (valproic acid) (15 mg/kg/day):

Weight (kg)	Weight (lb)	Total Daily Dose (mg)	Number of Capsules or Teaspoonfuls of Syrup Dose 1	Dose 2	Dose 3
10 - 24.9	22 - 54.9	250	0	0	1
25 - 39.9	55 - 87.9	500	1	0	1
40 - 59.9	88 - 131.9	750	1	1	1
60 - 74.9	132 - 164.9	1,000	1	1	2
75 - 89.9	165 - 197.9	1,250	2	1	2

A good correlation has not been established between daily dose, serum level and therapeutic effect, however, therapeutic serum levels for most patients will range from 50 to 100 mcg/ml. Occasional patients may be controlled with serum levels lower or higher than this range.

As the DEPAKENE dosage is titrated upward, blood levels of phenobarbital and/or phenytoin may be affected. (See PRECAUTIONS).

Patients who experience G.I. irritation may benefit from administration of the drug with food or by slowly building up the dose from an initial low level.

THE CAPSULES SHOULD BE SWALLOWED WITHOUT CHEWING TO AVOID LOCAL IRRITATION OF THE MOUTH AND THROAT.

HOW SUPPLIED: DEPAKENE (valproic acid) is available as orange-colored soft gelatin capsules of 250 mg valproic acid in bottles of 100 capsules (**NDC** 0074-5681-13), and as a red syrup containing the equivalent of 250 mg valproic acid per 5 ml as the sodium salt in bottles of 16 ounces (**NDC** 0074-5682-16).

M-M-R® II

MEASLES, MUMPS AND RUBELLA VIRUS VACCINE, LIVE (MSD)

Better

contains rubella virus strain RA 27/3

Convenient

one shot vaccinates against all three: measles, mumps, rubella

For a brief summary of prescribing information, please see following page.

MSD
MERCK SHARP & DOHME

Copyright © Merck & Co., Inc., 1980
All rights reserved.

Indications: *ATTENUVAX® (Measles Virus Vaccine, Live, Attenuated, MSD)*—Active immunization against measles (rubeola) in children 15 months of age or older.
BIAVAX®II (Rubella and Mumps Virus Vaccine, Live, MSD)—Simultaneous immunization against rubella and mumps in children 15 months of age to puberty. May be given as early as 12 months if that offers greater convenience in scheduling.
MERUVAX®II (Rubella Virus Vaccine, Live, MSD)—Immunization against rubella (German measles) in children 15 months of age to puberty. May be given as early as 12 months if that offers greater convenience in scheduling. May be useful for adolescent and adult males to prevent or control rubella outbreaks in circumscribed population groups. In postpubertal females vaccination must not be undertaken unless the woman is not pregnant, is susceptible to rubella (as shown by Hemagglutination Inhibition test), agrees not to become pregnant for next three months (also in immediate postpartum period), and is informed of frequent occurrence of self-limited arthralgia and possible arthritis beginning two to four weeks after vaccination.
M-M-R®II (Measles, Mumps and Rubella Virus Vaccine, Live, MSD)—Simultaneous immunization against measles, mumps, and rubella in children 15 months of age to puberty.
M-R-VAX®II (Measles and Rubella Virus Vaccine, Live, MSD)—Simultaneous immunization against measles (rubeola) and rubella (German measles) in children 15 months of age to puberty.
MUMPSVAX® (Mumps Virus Vaccine, Live, MSD)—Immunization against mumps for children 15 months of age or older and adults. May be given as early as 12 months if that offers greater convenience in scheduling.

Contraindications: Pregnancy or the possibility of pregnancy within three months following vaccination (see special considerations for ATTENUVAX below); hypersensitivity to neomycin; any febrile respiratory illness or other active infection; for measles-containing vaccines, active untreated tuberculosis; therapy with ACTH, corticosteroids (except as replacement therapy, e.g., for Addison's disease), irradiation, alkylating agents, or antimetabolites; blood dyscrasias, leukemia, lymphomas of any type, or other malignant neoplasms affecting the bone marrow or lymphatic systems; primary immunodeficiency states, including cellular immune deficiencies, hypogammaglobulinemic and dysgammaglobulinemic states.

Hypersensitivity to Eggs, Chicken, or Chicken Feathers: For measles- and/or mumps-containing vaccines, in patients hypersensitive to eggs, chicken, or chicken feathers, weigh benefits of immunization against potential risks of hypersensitivity reactions.

Pregnancy: *ATTENUVAX*—The effects of ATTENUVAX on fetal development are unknown at this time. Live attenuated measles virus vaccine should not be given to persons known to be pregnant; furthermore, pregnancy should be avoided for three months following vaccination. Reports have indicated that natural measles during pregnancy enhances fetal risk. Increased rates of spontaneous abortion, stillbirth, congenital defects, and prematurity have been observed subsequent to natural measles during pregnancy. There are no adequate studies of the attenuated (vaccine) strain of measles virus in pregnancy. However, it would be prudent to assume that the vaccine strain of virus is also capable of inducing adverse fetal effects for up to three months following vaccination.
Vaccine administration to postpubertal females entails a potential for inadvertent immunization during pregnancy. Theoretical risks involved should be weighed against the risks that measles poses to the unimmunized adolescent or adult. Advisory committees reviewing this matter have recommended vaccination of postpubertal females who are presumed to be susceptible to measles and not known to be pregnant. If a measles exposure occurs during pregnancy, one should consider the possibility of providing temporary passive immunity through the administration of immune serum globulin (human).

Precautions: Administer subcutaneously; *do not give intravenously.* Epinephrine should be available for immediate use should an anaphylactoid reaction occur. Should not be given less than one month before or after immunization with other *live* virus vaccines, with the exception that ATTENUVAX, MUMPSVAX, and/or MERUVAX II may be administered simultaneously. BIAVAX II may be administered simultaneously with ATTENUVAX. Monovalent or trivalent poliovirus vaccine, live, oral, may be administered simultaneously with ATTENUVAX and/or MUMPSVAX. Vaccinations should be deferred for at least three months following blood or plasma transfusions or administration of more than 0.02 ml human immune serum globulin per pound of body weight. However, rubella vaccine may be given prior to discharge to susceptible postpartum patients who received blood products, provided that a repeat HI titer is drawn six to eight weeks after vaccination to insure seroconversion; similarly, although rubella vaccine may be given in the immediate postpartum period to those nonimmune women who have received anti-Rh_0 (D) immune globulin (human) without interfering with vaccine effectiveness, a follow-up postvaccination HI titer should also be determined.
Attenuated measles, mumps, and rubella virus vaccines, live, given separately, may result in a temporary depression of tuberculin skin sensitivity; therefore, if a tuberculin test is to be done, it should be administered before or simultaneously with any of these virus vaccines. Vaccination may not result in seroconversion in 100 percent of susceptible subjects.
Measles-Containing Vaccines—Due caution should be employed in children with a history of febrile convulsions, cerebral injury, or any other condition in which stress due to fever should be avoided. The physician should be alert to the temperature elevation which may occur 5 to 12 days after vaccination. The occurrence of thrombocytopenia and purpura has been extremely rare.
Rubella-Containing Vaccines—Excretion of live attenuated rubella virus from the nose and throat has occurred in the majority of susceptible individuals 7 to 28 days after vaccination. There is no confirmed evidence to indicate that such virus is transmitted to susceptible persons who are in contact with vaccinated individuals. Consequently, transmission, while accepted as a theoretical possibility, is not regarded as a significant risk.

Adverse Reactions: To date, clinical evaluation of the combination vaccines has revealed those adverse reactions expected to follow administration of the monovalent vaccines given separately.
Measles-Containing Vaccines—Occasionally, moderate fever (101–102.9 F); less commonly, high fever (above 103 F); rarely, febrile convulsions. Infrequently, rash, usually minimal without generalized distribution. Reactions at injection site. Local reactions characterized by marked swelling, redness, and vesiculation at the injection site of attenuated live measles virus vaccines have occurred in children who previously received killed measles vaccine; the combination vaccines were not given under this condition in clinical trials.
Experience from more than 80 million doses of all live measles vaccines given in the U.S. through 1975 indicates that significant central nervous system reactions such as encephalitis and encephalopathy, occurring within 30 days after vaccination, have been temporally associated with measles vaccine approximately once for every million doses. In no case has it been shown that reactions were actually caused by vaccine. The Center for Disease Control has pointed out that "a certain number of cases of encephalitis may be expected to occur in a large childhood population in a defined period of time even when no vaccines are administered." However, the data suggest the possibility that some of these cases may have been caused by measles vaccines. The risk of such serious neurological disorders following live measles virus vaccine administration remains far less than that for encephalitis and encephalopathy with natural measles (one per thousand reported cases). There have been reports of subacute sclerosing panencephalitis (SSPE) in children who did not have a history of natural measles but did receive measles vaccine. Some of these cases may have resulted from unrecognized measles in the first year of life or possibly from the measles vaccination. Based on estimated nationwide measles vaccine distribution, the association of SSPE cases to measles vaccination is about one case per million vaccine doses distributed, far less than the 5 to 10 cases of SSPE per million cases of natural measles.
Rubella-Containing Vaccines—Adverse reactions include malaise, sore throat, headache, fever, and rash; mild local reactions such as erythema, local pain, induration, tenderness, and regional lymphadenopathy; thrombocytopenia and purpura; allergic reactions such as urticaria; and arthritis, arthralgia that is infrequently associated with signs of inflammation, and polyneuritis.
Moderate fever (101–102.9 F) occurs occasionally, and high fever (103 F) occurs less commonly. Rash occurs infrequently and is usually minimal without generalized distribution. Encephalitis and other nervous system reactions have occurred very rarely.
Transient arthritis, arthralgia, and polyneuritis vary in frequency and severity with age and sex, being greatest in adult females and least in prepubertal children. In children, joint reactions are rare and of brief duration if they do occur. In women, incidence rates for arthritis and arthralgia are generally higher than those seen in children (children: 0–3 percent; women: 12–20 percent), and the reactions tend to be more marked and of longer duration. Rarely, symptoms may persist for a matter of months. In adolescent girls, the reactions appear to be intermediate in incidence between those seen in children and in adult women. Even in older women (35–45 years), these reactions are generally well tolerated and rarely interfere with normal activities.
Mumps-Containing Vaccines—Parotitis and orchitis. Rarely, purpura and allergic reactions such as urticaria. Very rarely, encephalitis and other nervous system reactions. With the monovalent mumps vaccine, mild fever occurs occasionally, and fever above 103 F is uncommon.

Shipment, Storage, and Reconstitution: During shipment, to insure that there is no loss of potency, the vaccine must be maintained at a temperature of 10 C (50 F) or less. Before reconstitution, store vaccines at 2–8 C (35.6–46.4 F) and *protect from light.* Use only diluent supplied to reconstitute vaccines. If not used immediately, store reconstituted vaccines in a dark place at 2–8 C (35.6–46.4 F), and discard if not used within eight hours. Use a separate sterile syringe and needle for each individual patient to prevent transmission of infectious agents from one person to another.
Color: The color of the vaccine when reconstituted is yellow. ATTENUVAX is acceptable for use only if clear.

How Supplied: *ATTENUVAX® (Measles Virus Vaccine, Live, Attenuated, MSD)*—Single-dose vials of lyophilized vaccine, containing when reconstituted not less than the equivalent of 1,000 $TCID_{50}$ (tissue culture infectious doses) of measles virus vaccine expressed in terms of the assigned titer of the FDA Reference Measles Virus, and approximately 25 mcg neomycin.
BIAVAX®II (Rubella and Mumps Virus Vaccine, Live, MSD)—Single-dose vials of lyophilized vaccine, 0.5 ml when reconstituted as directed and containing not less than 1,000 $TCID_{50}$ of rubella virus vaccine, live, and 5,000 $TCID_{50}$ of mumps virus vaccine, live, expressed in terms of the assigned titer of the FDA Reference Rubella and Mumps Viruses, and approximately 25 mcg neomycin.
MERUVAX®II (Rubella Virus Vaccine, Live, MSD)—Single-dose vials of lyophilized vaccine, 0.5 ml when reconstituted as directed and containing not less than the equivalent of 1,000 $TCID_{50}$ of rubella virus vaccine expressed in terms of the assigned titer of the FDA Reference Rubella Virus, and approximately 25 mcg neomycin.
M-M-R®II (Measles, Mumps and Rubella Virus Vaccine, Live, MSD)—Single-dose vials of lyophilized vaccine, 0.5 ml when reconstituted as directed and containing not less than 1,000 $TCID_{50}$ of measles virus vaccine, live, attenuated, 5,000 $TCID_{50}$ of mumps virus vaccine, live, and 1,000 $TCID_{50}$ of rubella virus vaccine, live, expressed in terms of the assigned titer of the FDA Reference Measles, Mumps, and Rubella Viruses, and approximately 25 mcg neomycin.
M-R-VAX®II (Measles and Rubella Virus Vaccine, Live, MSD)—Single-dose vials of lyophilized vaccine, 0.5 ml when reconstituted as directed and containing not less than 1,000 $TCID_{50}$ of measles virus vaccine, live, attenuated, and 1,000 $TCID_{50}$ of rubella virus vaccine, live, expressed in terms of the assigned titer of the FDA Reference Measles and Rubella Viruses, and approximately 25 mcg neomycin.
MUMPSVAX® (Mumps Virus Vaccine, Live, MSD)—Single-dose vials of lyophilized vaccine, containing when reconstituted not less than 5,000 $TCID_{50}$ of mumps virus vaccine expressed in terms of the assigned titer of the FDA Reference Mumps Virus, and approximately 25 mcg neomycin.
Each of these vaccines is supplied as a single-dose vial with a disposable syringe containing diluent and fitted with a 25-gauge, 5/8" needle, and as a box of 10 single-dose vials with an accompanying box of 10 diluent-containing disposable syringes with affixed needles.

Instructions for Authors

General Information.—Send manuscripts by first-class (**not** registered) mail to the Chief Editor, Gilbert B. Forbes, MD, Box 777, 601 Elmwood Ave, Rochester, NY 14642. Designate one author as correspondent and provide his/her address and telephone number. Manuscripts are received with the understanding that they are not under simultaneous consideration by another publication. Accepted manuscripts become the permanent property of the *American Journal of Diseases of Children* and may not be published elsewhere without permission from the publisher (AMA).

In view of the provisions of *The Copyright Revision Act of 1976*, effective Jan 1, 1978, the author(s) of manuscripts, letters to the editor, and book reviews accepted for publication in the JOURNAL will be required to sign and date the following statement: "In consideration of the AMA taking action in reviewing and editing my/our submission, the author(s) undersigned hereby transfers, assigns, or otherwise conveys all copyright ownership to the AMA in the event that such work is published by the AMA."

Manuscript Preparation.—All the elements of a manuscript must be submitted in **triplicate, double-spaced throughout**. Use heavy-duty white bond paper, 21.6 × 27.9 cm, and 4-cm margins. If a word processor is used, do not justify lines. The style of writing should conform to proper English usage and syntax. All measurements are to be in metric units, temperatures in Centigrade.

All accepted manuscripts are subject to copy editing. The corresponding author will receive an edited typescript and layout for approval. Forms for ordering reprints are included with the edited typescript. Proofs will be sent for approval if requested by the author and if printing deadlines permit. The author is responsible for all statements in his/her work, including changes made by the copy editor.

Titles.—Titles should be short, specific, and clear. They should not exceed 42 characters per line, including punctuation and spaces, and be limited to two lines. The title page should include the full names and academic affiliations of all authors, the address to which requests for reprints should be sent, and, if the manuscript was presented at a meeting, the name of the organization, place, and date on which it was read.

Abstract.—Provide an abstract (135-word maximum) of the article, including statement of the problem, method of study, results, and conclusions. The abstract replaces the summary.

Informed Consent.—Manuscripts reporting the results of experimental investigations on humans must include a statement to the effect that informed consent was obtained from the parents or guardians after the nature of the procedure(s) had been fully explained.

Clinical Memoranda.—Brief accounts of interesting observations and clinical situations. Limited to 800 words plus one table or illustration; abstract unnecessary. Submit in triplicate, double-spaced. Copyright assignment required.

Letters to the Editor.—Correspondence pertaining to material published in the JOURNAL. Limit 500 words. Submit in triplicate, double-spaced, and clearly marked "For publication." Copyright assignment required.

References.—List in order of their appearance in the text, and type double-spaced, in the following manner:

1. Applebaum MM, Thaler MM: Reye syndrome without initial hepatic involvement. *Am J Dis Child* 1977; 131:295-296.
2. Koller LR: *Ultraviolet Radiation*, ed 2. New York, John Wiley & Sons, 1965, 141-160.
3. Daughaday WH: The adenohypophysis, in Williams RH (ed): *Textbook of Endocrinology*, ed 5. Philadelphia, WB Saunders, 1974: 31-79.

Do not include unpublished data, personal communications, or manuscripts "in preparation" or "submitted" in the list of references. Such material, if essential, may be incorporated in the body of the article.

Illustrations.—Submit only high-contrast glossy prints in triplicate, unmounted and untrimmed. Preferred size is 12.7 × 17.3 cm (5 × 7 in). Figure number, name of first author, and arrow indicating "top" should be typed on a gummed label and affixed to the back of each illustration. Lettering must be legible after reduction to column size. Magnification and stain should be provided for histologic sections.

For illustrations in full color submit 35-mm, positive color transparencies, mounted in cardboard and carefully packaged. Do not submit glass-mounted transparencies; do not submit color prints. The fee is $275 for up to six square-finished color illustrations that can be arranged on one page. A letter of intent to pay the fee must accompany submission.

Legends.—Legends for illustrations should be typed double-spaced, beginning on a separate sheet of paper (40-word maximum for each).

Acknowledgments.—Illustrations and tables from other publications must be suitably acknowledged, and accompanied by written permission from publisher and author.

Photographic Consents.—A signed statement of consent from **both** parents (or guardian) or the persons involved must accompany all photographs of patients in which a possibility of identification exists. It is not sufficient to cover the eyes to mask identity.

Tables.—Each table should be typed double-spaced, including all headings, on a separate sheet of 21.6 × 27.9 cm paper. If a table must be continued, use a second sheet and repeat all heads. Each table must have a title.

Uniform Requirements.—Further details on manuscript preparation are given in the document *Uniform Requirements for Manuscripts Submitted to Biomedical Journals* prepared by the International Steering Committee of Medical Editors. Reprints of this document are available by directing requests to this journal: Scientific Publications, 535 N Dearborn St, Chicago, IL 60610.

Increasing resistance of

Brief Summary.
Consult the package literature for prescribing information.

Indications and Usage: Ceclor®(cefaclor, Lilly) is indicated in the treatment of the following infections when caused by susceptible strains of the designated microorganisms:
Otitis media caused by *Streptococcus pneumoniae (Diplococcus pneumoniae), Haemophilus influenzae,* staphylococci, and *S. pyogenes* (group A beta-hemolytic streptococci).
Appropriate culture and susceptibility studies should be performed to determine susceptibility of the causative organism to Ceclor.

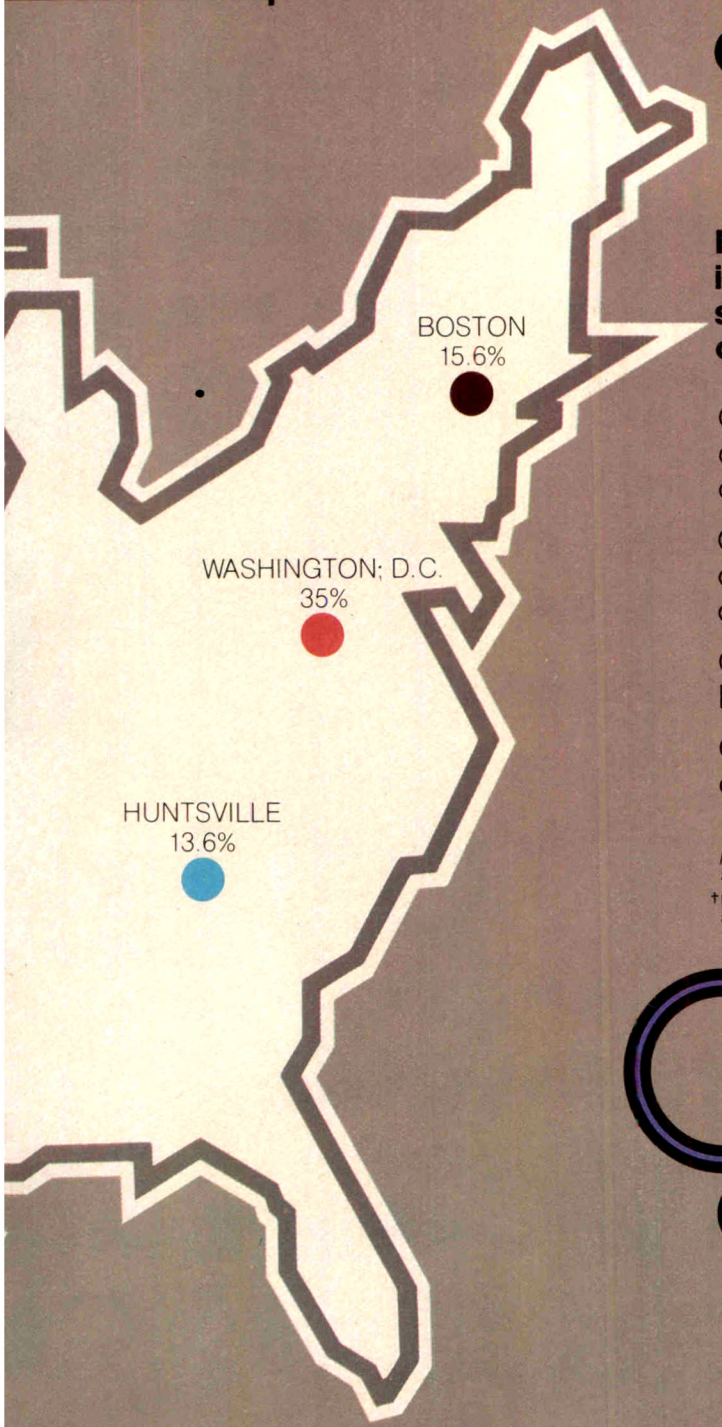
Contraindication: Ceclor is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

Warnings: IN PENICILLIN-SENSITIVE PATIENTS, CEPHALOSPORIN ANTIBIOTICS SHOULD BE ADMINISTERED CAUTIOUSLY. THERE IS CLINICAL AND LABORATORY EVIDENCE OF PARTIAL CROSS-ALLERGENICITY OF THE PENICILLINS AND THE CEPHALOSPORINS, AND THERE ARE INSTANCES IN WHICH PATIENTS HAVE HAD REACTIONS TO BOTH DRUG CLASSES (INCLUDING ANAPHYLAXIS AFTER PARENTERAL USE).
Antibiotics, including Ceclor® (cefaclor, Lilly), should be administered cautiously to any patient who has demonstrated some form of allergy, particularly to drugs.

Precautions: If an allergic reaction to cefaclor occurs, the drug should be discontinued, and, if necessary, the patient should be treated with appropriate agents, e.g., pressor amines, antihistamines, or corticosteroids.
Prolonged use of cefaclor may result in the overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection occurs during therapy, appropriate measures should be taken.
Positive direct Coombs tests have been reported during treatment with the cephalosporin antibiotics. In hematologic studies or in transfusion cross-matching procedures when antiglobulin tests are performed on the minor side or in Coombs testing of newborns whose mothers have received cephalosporin antibiotics before parturition, it

Haemophilus influenzae in otitis media...

a valid concern



In many areas of the country, increasing numbers of *H. influenzae* show resistance to conventional antibiotic therapy.[1-3]

Ceclor is effective in the treatment of otitis media†, including that due to some ampicillin-resistant strains of *H. influenzae*.[4-9]

Ceclor has been shown to be clinically and bacteriologically effective in treating otitis media due to susceptible organisms.[10]

Ceclor is available in two pleasant-tasting liquids.

Ceclor provides effective single-agent antibiotic therapy for otitis media.

Note: Ceclor is contraindicated in patients with known allergy to the cephalosporins and should be given cautiously to penicillin-allergic patients.

†Due to susceptible strains of *Streptococcus pneumoniae, H. influenzae,* staphylococci, and *S. pyogenes.*

125-mg/5-ml and 250-mg/5-ml oral suspensions

Ceclor®
cefaclor

should be recognized that a positive Coombs test may be due to the drug.

Ceclor® (cefaclor, Lilly) should be administered with caution in the presence of markedly impaired renal function. Under such a condition, careful clinical observation and laboratory studies should be made because safe dosage may be lower than that usually recommended.

Usage in Pregnancy—Although no teratogenic or antifertility effects were seen in reproduction studies in mice and rats receiving up to 12 times the maximum human dose or in ferrets given three times the maximum human dose, the safety of this drug for use in human pregnancy has not been established. The benefits of the drug in pregnant women should be weighed against a possible risk to the fetus.

Usage in Infancy—Safety of this product for use in infants less than one month of age has not been established.

Adverse Reactions: In clinical studies in 1493 patients, adverse effects considered related to cefaclor therapy were uncommon and are listed below:

Gastrointestinal symptoms occurred in about 2.5 percent of patients and included diarrhea (1 in 70) and nausea and vomiting (1 in 90).

Hypersensitivity reactions were reported in about 1.5 percent of patients and included morbilliform eruptions (1 in 100). Pruritus, urticaria, and positive Coombs tests each occurred in less than 1 in 200 patients.

Other effects considered related to therapy included eosinophilia (1 in 50 patients) and genital pruritus or vaginitis (less than 1 in 100 patients).

Causal Relationship Uncertain—Transitory abnormalities in clinical laboratory test results have been reported. Although they were of uncertain etiology, they are listed below to serve as alerting information for the physician.

Hepatic—Slight elevations in SGOT, SGPT, or alkaline phosphatase values (1 in 40).

Hematopoietic—Transient fluctuations in leukocyte count, predominantly lymphocytosis occurring in infants and young children (1 in 40).

Renal—Slight elevations in BUN or serum creatinine (less than 1 in 500) or abnormal urinalysis (less than 1 in 200).

Is Propranolol Alone Really Beneficial in Neonatal Thyrotoxicosis?

Bradycardia and Hypoglycemia Evoke the Doctrine of *Primum non Nocere*

In the July issue of the JOURNAL (134:707-708, 1980), Newman et al[1] described an infant with neonatal thyrotoxicosis treated solely with propranolol hydrochloride, which resulted in episodic bradycardia but no improvement in the patient's clinical status. Since this regimen has been recently described as the "treatment of choice" for neonatal thyrotoxicosis, it seems appropriate to call attention to the limitations and possible complications of using only propranolol in this condition.

Smith and Howard[2] seem to have been the first to report the use of propranolol in neonatal thyrotoxicosis, in conjunction with propylthiouracil, Lugol's solution, digitalization, and sedation. These authors recommended that in addition to thyroid blockade, propranolol in a dose of 2 mg/kg be used as standard therapy for the management of neonatal thyrotoxicosis. In the following year, Pemberton et al[3] described an infant with this condition in whom only propranolol was used as therapy; results were apparently satisfactory. Subsequently Pearl and Chambers[4] used only propranolol in a 1,625-g premature infant with neonatal thyrotoxicosis and were favorably impressed.

It is important that those physicians who elect to use β-adrenergic blocking agents in the newborn be familiar with the profound effects these agents are capable of exerting on the fetus, newborn, and child. When propranolol is administered during pregnancy, the infant at birth is at risk for severe depression, manifested by bradycardia and hypoglycemia, both of which are attributable to the β-adrenergic effects of the drug.[5-9] The infant born of a propranolol-treated mother studied by Cottrill et al[7] had no measurable blood glucose at birth; after intravenous 10% dextrose in water the level rose to 15 mg/dL. The infant's plasma propranolol level rose from a value of 42 ng/mL at birth to 90 ng/mL at 4 hours of age. This latter value is comparable to that achieved by the infant of Pemberton et al[3] on propranolol treatment for neonatal thyrotoxicosis (see below). Lieberman et al[8] found that the probability of fetal or neonatal death was significantly higher ($P < .05$) when the mother had been treated with propranolol. Pruyn et al[9] examined ten infants born of mothers who had been on long-term propranolol treatment regimens: three of their babies exhibited hypoglycemia and five had intrauterine growth retardation.

That the older child may also be at risk for hypoglycemia was originally reported by Mackintosh,[10] who described a 9-year-old child receiving propranolol who experienced a grand mal convulsion with a blood glucose value of 12 mg/dL following an overnight fast. The fast was repeated together with propranolol therapy and clinical hypoglycemia again ensued. Similar findings were described by Feller[11] in two propranolol-treated children, the most severely affected of whom was found unconscious and convulsing after fasting overnight, with a blood glucose value of 15 mg/dL.

Hesse and Pedersen described cyanosis, stupor, and pallor in previously healthy siblings (aged 20 months and 3 years) who accidentally ingested 150 mg of propranolol hydrochloride between the two of them.[12] They were not fasting, but the younger had a plasma glucose level of 14 mg/dL and the older a level of 50 mg/dL. They responded promptly to intravenous glucose therapy. Gillette et al[13] administered propranolol to 64 children of varying ages in a study designed to determine the effectiveness of that agent in the management of several cardiac conditions. Ten showed complications of therapy, and treatment was stopped in four cases: two with bradycardia (30 and 50 beats per minute), one with congestive heart failure, and one with somnolence. The infant treated by Pearl and Cham-

bers[4] exhibited vomiting, which is a rare complication of propranolol therapy. Their patient vomited, sometimes in a projectile manner, from the 38th to the 53rd day of life. Vomiting stopped 24 hours after propranolol was discontinued.

Mosier has outlined the contraindications to β-blockade in childhood thyrotoxicosis as follows[14]:

Congestive heart failure that does not respond to digitalis glycosides and diuretics

Atrioventricular block

Obstructive airway disease (including bronchial asthma and allergic rhinitis); (even eyedrops containing the β-blocker timolol, used to treat glaucoma, have provoked severe reactions in patients with bronchial asthma[15] and have aggravated congestive heart failure[16])

Patients taking insulin or oral hypoglycemia agents

Therapeutic failures with propranolol, such as that described by Newman et al in neonatal thyrotoxicosis, have also been noted in adult thyrotoxic patients. Eriksson et al[17] and Jamison and Done[18] have described adults in whom thyroid storm was not prevented by propranolol therapy. Since there may be a wide range of effective propranolol dosage from patient to patient and since neonatal thyrotoxicosis itself varies in severity, the variables faced by the physician in supervising treatment are formidable.

There is an unusual disparity from one study to another in the dosage of propranolol required to achieve a beneficial response, as judged by cardiac and respiratory rates. The two infants described by Smith and Howard[2] required a maximum of 4 to 6 mg/day of propranolol (but they also received propylthiouracil and Lugol's solution). The patient of Pemberton et al[3] received only propranolol, beginning with 2 mg/day at 2 weeks of age and increased according to pulse rate until the baby at 5 weeks was getting 32 mg/day. The latter dosage gave a plasma propranolol concentration of 89 ng/mL two hours after treatment. Pearl and Chambers[4] gave 1.5 mg of propranolol per day beginning at the age of 1 week and increased dosage according to heart rate until at 7 weeks 28 mg/day was being given. In the patient of Newman et al, episodic sinus bradycardia developed at a propranolol dose of only 6 mg/day; clinical improvement did not occur until propylthiouracil and Lugol's solution were added to the treatment regimen and the propranolol was discontinued.

There may be a place for propranolol, along with thionamides and perhaps other medications, in the treatment of neonatal thyrotoxicosis, but there seems little indication for using it alone. The known hazards associated with its use must be weighed against any benefits, and if it is administered, adequate monitoring of the patient for bradycardia, hypoglycemia, and other manifestations of β-blockade must be carried out. Since the relationship of plasma propranolol levels to clinical response and symptomatology is not clear, it would seem important to make such measurements in this rare syndrome.

Pancuronium and Abnormal Abdominal Roentgenograms

Robert G. Dillard, MD; James E. Crowe, MD; Thomas E. Sumner, MD

• Pancuronium bromide treatment in severely ill, mechanically ventilated infants has been shown to result in lower peak transpulmonary pressures, with an accompanying lower-than-expected incidence of pneumothorax. Infants treated with pancuronium often demonstrate an ominous abdominal roentgenographic finding: the "gasless abdomen." Of 38 mechanically ventilated infants, 22 of 24 pancuronium-treated infants (as compared with four of 14 untreated infants) had diminished or absent bowel gas. There was no significant difference between the two groups with regard to birth weight, mortality, or incidence of respiratory distress syndrome. Pancuronium prevents swallowing of air but does not inhibit gut peristalsis, thus accounting for the evacuation of abdominal gas three hours or more after administration of the drug. Clinicians who treat infants with pancuronium should be aware of the phenomenon, to avoid needless roentgenographic studies.

(*Am J Dis Child* 134:821-823, 1980)

Pancuronium bromide, a neuromuscular blocking agent with little autonomic ganglionic blocking activity,[1] is used to manage neonates who require mechanical ventilation. Treated infants have lower peak transpulmonary pressures and an apparently lower incidence of pneumothorax.[2] With the drug's introduction into our intensive care nursery (ICN), we recognized that its use is often associated with an ominous roentgenographic finding, the "gasless abdomen." In an attempt to analyze the association and to delineate the time course of its occurrence, records and roentgenograms of mechanically ventilated infants in whom pancuronium had and had not been used were reviewed.

SUBJECTS AND METHODS

Medical records and roentgenograms of 83 consecutively ventilated neonates cared for during 1978 in our ICN were reviewed by one of us (R.G.D.). Subjects were selected for study if serial roentgenograms were available that allowed analysis of bowel-gas patterns before, during, and, if the patient survived, after the period of mechanical ventilation. The films for these study infants were reviewed independently by pediatric radiologists (J.E.C. and T.E.S.) without knowledge of the treatment regimen. Roentgenograms were interpreted to have "normal," "borderline," or "diminished" bowel gas.

RESULTS

Thirty-eight of the 83 infants had had roentgenograms that met the criteria. Twenty-four of the 38 infants (63%) had been treated with pancuronium, as compared with 20 of 45 infants (45%) with roentgenograms inadequate for serial evaluation. The difference was not significant ($\chi^2 = 2.18$, $P \geq .1$).

The two radiologists were in complete agreement with regard to their ratings of bowel-gas patterns. Twenty-five infants had films that demonstrated diminished bowel gas, one case was borderline, and 12 infants had normal gas patterns on all films viewed. In analyzing the results, 22 of the 24 pancuronium-treated infants had diminished or borderline patterns,

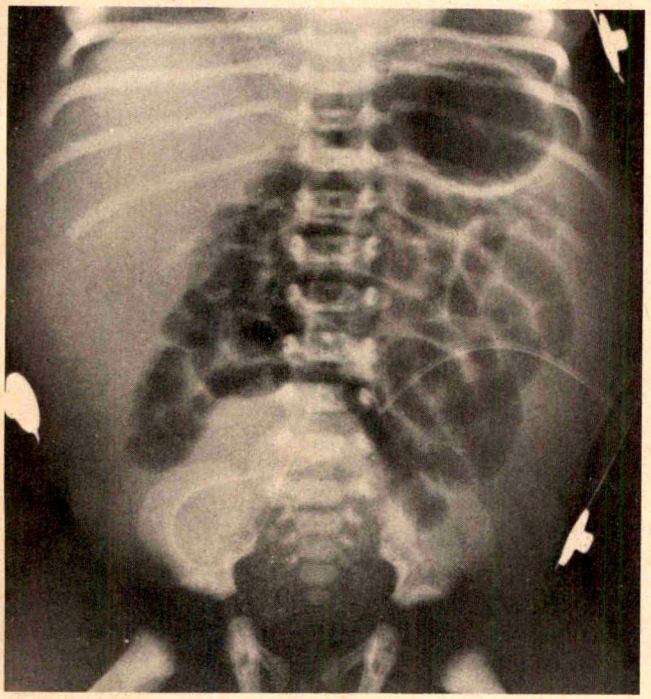

Fig 1.—Roentgenogram taken before administration of pancuronium bromide.

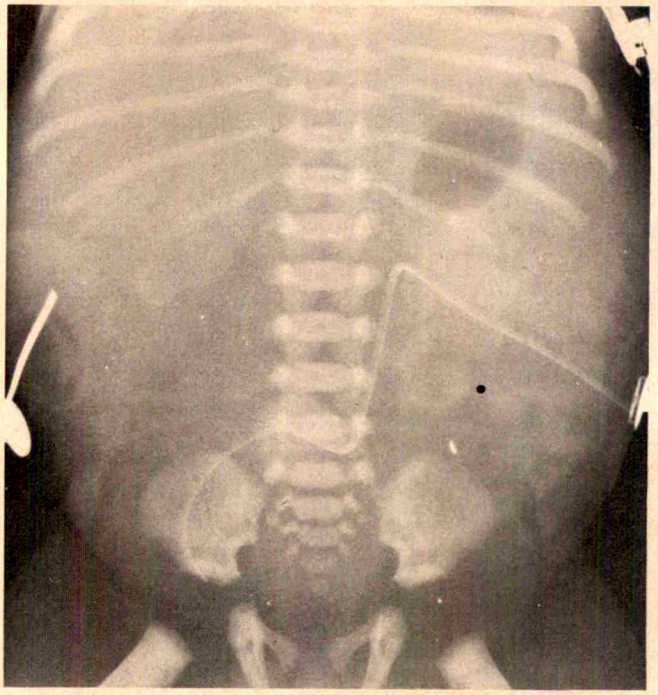

Fig 2.—Roentgenogram taken four hours after administration of pancuronium bromide.

whereas only four of the 14 infants not treated had diminished patterns ($\chi^2 = 19.2$, $P < .001$, Yates' correction).

The treated infants' mean birth weight was 1,923 g (range, 800 to 3,824 g); the untreated group mean was 1,661 g (range, 710 to 3,399 g). The difference was not significant (Kolmogorov-Smirnoff test, $P = .97$). Seventy-one percent of the treated infants died, as compared with 50% of the untreated infants ($\chi^2 = 2.67$, $P > .1$). Seventy-nine percent of the pancuronium-treated infants had the respiratory distress syndrome (RDS), as compared with 71% of the untreated group ($\chi^2 = .306$, $P > .5$). Of the infants with RDS, 69% of the treated infants died as compared with 50% of the untreated infants ($\chi^2 = .94$, $P > .3$).

Of the 22 infants treated with pancuronium and showing diminished gas patterns, seven had roentgenograms taken within two hours of administration of the first dose of the drug. Bowel gas patterns were normal in six of seven. Twenty of the 22 treated infants demonstrated diminished bowel gas patterns on films taken three hours or later after initiation of treatment. The remaining two of the 22 infants had normal gas patterns six hours after administration of the first dose. Subsequent roentgenograms showed absent gas in both.

Figures 1 and 2 are roentgenograms of a representative study infant taken immediately before and four hours after administration of the drug that demonstrate the change in bowel-gas patterns.

REPORT OF CASES

These two cases demonstrate effects of pancuronium on normal and diseased gastrointestinal (GI) tracts.

Case 1.—A 2-kg boy born at 34 weeks' gestation had severe RDS that required mechanical ventilation. His treatment also included administration of pancuronium. On his 5th day of life, while he was still receiving ventilator treatment, a pneumoperitoneum developed. Water-soluble contrast material was instilled into his stomach via a nasogastric tube to rule out a perforated viscus. No perforation was noted and the contrast material passed through the gasless GI tract normally. The pneumoperitoneum was thought to have arisen from a thoracic leak. The patient's course was further complicated by bronchopulmonary dysplasia that required an extended period of mechanical ventilation and supplemental oxygen. He was discharged at 74 days of age.

Case 2.—A 10-day-old, 1.2-kg boy was transferred to our ICN because of abdominal distention. The baby was moribund, with marked increase in abdominal girth. Roentgenograms revealed gaseous distention and multiple areas of pneumatosis intestinalis. Air was present in the portal venous system as well. On the basis of the clinical and roentgenographic findings, a diagnosis of necrotizing enterocolitis was made. Respiratory failure shortly after admission necessitated ventilatory assistance. Pancuronium was used as well. Subsequent abdominal films revealed evacuation of a significant amount of abdominal gas. However, several loops of bowel remained distended and their configuration remained unchanged over three days of conservative medical management. At the time of surgery four days after admission, several segments of gas-filled necrotic bowel were excised. The patient required an extended course of total parenteral nutrition and died as a result of complications of the latter.

COMMENT

Analysis of our data shows a dis-

tinct association between use of pancuronium and diminished or absent bowel gas. Twenty-two of the 24 treated infants, as compared with four of the 14 untreated infants, had abnormal bowel-gas patterns. Siegle has recently described the occurrence of the "gasless abdomen" in two infants treated with pancuronium.[3]

Abdominal films of normal neonates show considerable amounts of bowel gas within three to six hours from birth as a result of air swallowing and effects of gut peristalsis. Infants paralyzed with pancuronium cannot swallow. However, the absence of autonomic ganglionic blockade characteristic of other curare-like drugs permits peristalsis to continue. Any intestinal gas present in the intestines at the onset of drug therapy is evacuated, and without swallowing no further air is introduced.

Although this study did not attempt to confirm this hypothesis as causative of the association, the evidence from case 1 does demonstrate that gut peristalsis is unaffected by pancuronium administration. Contrast material introduced into a previously "gasless abdomen" is evacuated within normal time periods.

Analysis of the time between administration of drug and presence of abnormal gas patterns showed that approximately three hours must pass before evidence of diminished gas appears. Neonates with absent bowel gas on films taken within three hours must be evaluated for other causes of diminished abdominal gas.

Intestinal gas may not be evacuated by pancuronium-treated infants who have abnormal GI tracts. Case 2 illustrates that gas may persist in diseased segments of bowel affected by necrotizing enterocolitis. The infant who persists in having bowel gas three to six hours after administration of adequate amounts of pancuronium should be investigated for the possibility of abnormal gastrointestinal function.

Knowledge of the association between diminished or absent bowel gas and pancuronium use may prevent unnecessary studies of an infant's GI tract. However, it should be remembered that because of the almost universal occurrence of the phenomenon in treated infants, more serious conditions may be overlooked. Likewise, persistent bowel gas in treated infants should be recognized as an abnormal circumstance and investigated accordingly.

Cell-Mediated Immune Defects and Infection

A Study of Malnourished Hospitalized Children

Jean M. Carney, MD; Margaret S. Warner, MD; Thomas Borut, MD; William Byrne, MD; Marvin Ament, MD; James D. Cherry, MD; E. Richard Stiehm, MD

• **Severe protein calorie malnutrition in children in developing countries has been characterized by noticeable depression of cell-mediated immunity and an increased manifestation of infectious illnesses. We studied 23 hospitalized US children whose admitting diagnoses included severe malnutrition to see if similar findings existed. Children were divided into two groups based on the percentage of E rosettes (T cells) prior to nutritional therapy. Those with E rosette values less than 50% were considered to have noticeably abnormal cell-mediated immunity. Eleven of the 23 patients who had rosette values less than 50% had 18 clinical infections, including four episodes of sepsis. One of the 23 children with normal (>50%) E rosettes had one minor infection. It was concluded that depressed cellular immunity as measured by E rosettes is associated with an increased incidence of infectious illness in the malnourished hospitalized pediatric patient in the United States. Other defects in host defenses, ie, defects in complement and phagocytic function, may also have contributed to the increased number of clinical infections noted in these patients.**

(*Am J Dis Child* 134:824-827, 1980)

Children in developing countries with protein calorie malnutrition (PCM) manifest severe and prolonged infectious illnesses.[1] The primary, but not the only, immunologic problem in these children is defective cell-mediated immunity (CMI).[2,3] This defect is characterized by decreased delayed cutaneous hypersensitivity,[4] decreased lymphocyte transformation to phytohemagglutinin (PHA), and low numbers and percentages of T cells.[5] The number of T cells, assessed by their ability to form rosettes with sheep erythrocytes (E rosettes), is a sensitive index of cellular immunity. The degree of E rosette depression generally correlates with the severity of the cellular immune deficit.[6]

Most studies of immune defects in malnutrition have been done on children in developing countries.[7] Recently, investigators have studied malnourished hospitalized adults in this country with PCM.[8-11]

In this report, we assess the relationship between infection and depressed CMI in 23 malnourished hospitalized children in Los Angeles. E rosettes, rather than delayed hypersensitivity skin-test responsiveness were used to evaluate depressed CMI because of known decreased skin-test responsiveness in young normal pediatric patients.[12]

MATERIALS AND METHODS

Patients

All subjects were chosen from the inpatient pediatric service at UCLA hospital and clinics, Los Angeles. All were younger than 18 years of age and had clinical evidence of malnutrition noted in their admission history and on physical examination.

To be included in the study, patients had to have weights less than the fifth percentile for age by National Center for Health Statistics (NCHS) Growth Charts as published in 1976.[13] Weight for height was also obtained from these growth charts.

They were further classified in accordance with the Harvard Standard Weight for Age where 100% of standard is comparable with the 50th percentile on the growth chart.[14] Patients with weight less than 60% of the Harvard standard were judged to have severe PCM and those less than 80% of standard had moderate PCM. Harvard Standard Height for Age was used to estimate the presence of long-term nutritional deprivation. Patients less than 90% of height for age were considered to have chronic severe malnutrition.

The patients' charts were reviewed for age, sex, and admitting diagnosis. Those with illnesses lasting less than one month were described as acute, whereas those with illnesses longer than one-month's duration were considered chronic. Patients with a known primary immunodeficiency diagnosis were excluded. The presence of culture-proved infection and its relation to the time of immune evaluation and the time of nutritional therapy was recorded. Mode of nutritional therapy was also noted, ie, oral feeding, with supplementary peripheral intravenous (IV) feeding or placement of a central venous catheter for total or partial alimentation.

Initial CMI and nutritional assessments were done on all patients before adequate nutritional replacement was begun. Time of adequate nutritional therapy was determined by chart records of steady weight gain and adequate calorie intake.

Cellular immunity was evaluated by E rosettes, absolute lymphocyte count, and PHA stimulation. Humoral immunity was evaluated by quantitative immunoglobulins in some patients. No attempt was made to quantitate possible lymphocyte or immunoglobulin loss from the gastrointestinal (GI) tract. No patients had congenital lymphangectasia to suggest GI loss of lymphocytes. The patients were divided into two groups based on evidence of defective CMI, as measured by E rosettes. Those with E rosette values less than 50% were considered to have evidence of noticeable abnormal CMI (group 1). Those with E rosette values greater than or equal to 50% were considered to have normal or near-normal CMI (group 2). These divisions of rosette values were based on the data of Ferguson et al.[5] Subsequent repeated E rosette determinations were attempted on those patients whose initial values were less than 50%. Laboratory nutritional evaluation for this study was generally limited to complete blood cell count and total serum protein and serum albumin levels; some patients also underwent iron and transferrin studies.

E Rosettes

Heparinized blood was diluted 1:1 with normal saline and mononuclear cells were separated on a Ficoll-Hypaque gradient (sp g, 1.077). The separated cells were washed twice, counted, and adjusted to a concentration of 5×10^6/mL. Fifty microliters of this cell suspension was added to an equal

†Total is more than number of patients in group because several patients had more than one infection.

volume of a sheep's RBC (S-RBC) suspension (5.0×10^7 cell/mL) in heat inactivated (S-RBC) absorbed human AB serum. The mixture was centrifuged at 150 g for five minutes and incubated overnight at 4 °C. Cells were gently resuspended and the number of lymphocytes binding at least three or more S-RBCs were counted. Duplicate samples were run on each specimen, with a normal young adult control included each day (E rosette percentages of young adult controls in this laboratory do not differ significantly from normal pediatric controls). Results were expressed as percent of lymphocytes forming rosettes and as an absolute number in some patients, based on total lymphocyte count. A total lymphocyte number would normally be greater than 2,000, and 60% would be the normal percent of T cells, so a count greater than 1,200 would be a normal number of T cells.

PHA Stimulation

Mononuclear cells were resuspended at a concentration of 1.0×10^6 cells/mL in asynthetic liquid tissue culture media developed at Roswell Park Memorial Institute (RPMI 1640) with 20% heat-inactivated human AB serum. One hundred microliters of the cell suspension was incubated in tissue culture plates in triplicate with three dilutions of PHA and without PHA in a humidified 5% CO_2 37 °C incubator for 72 hours.

Two microcuries of tritiated thymidine was added to each culture and cultures were harvested 18 hours later onto glass fiber-filter disks, then dried and counted in a scintillation counter. Results were expressed as an index or ratio of the highest counts of the stimulated cells to the unstimulated cells. A stimulation index of less than 40 was considered abnormal. Normal control samples were run daily.

Quantitative Immunoglobulins

Quantitative immunoglobulins were performed using radioimmunodiffusion. Because normal values vary for different-aged children, results were evaluated as normal, increased, or decreased more than 1 SD from normal for age.

Nutritional Studies

Nutritional studies were done by the UCLA Hospital Clinical Laboratory. Laboratory normal values for these studies were as follows: albumin, >3.2 g/dL; total protein, >6 g/dL; serum iron, >50 μg/dL, serum transferrin, >280 μg/dL; and hemoglobin, >10 g/dL.

RESULTS
Clinical Evaluation

Twenty-three patients were examined; all were less than the fifth percentile weight for age on NCHS growth charts. When evaluated by the Harvard Standard Weight for Age, 16 (69%) of the children were 60% to 80% of the standard and the other seven (31%) were less than 60% of the standard, characteristic of moderate to severe PCM. Sixteen of the children had heights less than 90% of the Harvard Standard Height for Age, characteristic of long-standing nutritional deprivation. Eighteen patients (78%) were less than the fifth percentile weight for height and five (12%) were at or below the 25th percentile of the NCHS growth charts.

Fifteen patients were boys and eight were girls. Twelve were less than 1 year of age and 11 were 1 to 18 years of age. Admitting diagnoses were primary GI disease (11 patients) or miscellaneous other conditions (12 patients). The latter included starvation in three Vietnamese refugee infants and severe failure-to-thrive in one infant secondary to maternal neglect. Three others had chronic pulmonary disease, asthma, cystic fibrosis, and interstitial fibrosis. Two had anorexia nervosa. One patient had granulocytopenia that resolved spontaneously and one was hyperthyroid. Twenty-two of the 23 patients had illnesses of greater than one month's duration, nine patients required placement of a central venous catheter, whereas 14 required only peripheral IV and oral alimentation.

When patients were grouped according to CMI as measured by E rosettes, there were no significant differences between those children in group 1 and group 2 in weight for age, height for age, or weight for height.

UNIVERSITY COLLEGE OF MEDICINE LIBRARY

The mean age was 3.48 years for group 1 and 5.42 years for group 2. Five patients in group 1 and seven patients in group 2 were 12 months old or younger. Four children with normal or only slightly abnormal E rosette values required central vein lines and five of those with noticeably abnormal E rosette values received central alimentation.

Immune Evaluation

Immune studies were performed usually within 48 to 72 hours of admission, which would have been during the time of an infectious illness in eight patients in group 1. In three patients in whom clinical infections developed while they were in the hospital, the immune studies were performed prior to the clinical manifestations. In the one child who had multiple episodes of septicemia, the immune studies were done between the third and fourth septic episodes. No infections were associated with the central feeding catheters.

Immunologic studies in group 1 and group 2 patients are compared in Table 1. By definition, E rosette evaluation was done on all 23 children since subsequent grouping of CMI was based on these values. The mean E rosette value of group 1 was 40 compared with 63 in group 2. Eight patients from group 1 were reexamined ten to 14 days later and their rosette percentages had returned to a normal range. Two children in this group were reexamined three and six months later and normal E rosette percentages were observed. The means of the absolute number of T lymphocytes calculated from seven of 11 patients in group 1 and seven of 12 patients in group 2 were 1,502/cu mm and 2,773/cu mm, respectively. EA rosettes, a measurement of B cells by presence of crystallizable fragment (Fc) receptors, were available on eight patients in group 1 and nine in group 2. There were no differences between the two groups in either numbers or percentages of EA rosettes. Indices of PHA stimulation were obtained on 22 patients. Depressed PHA values were seen in nine patients, five of 11 in group 1 and four of 11 examined in group 2. However, the mean PHA index for the two groups was not significantly different. The mean absolute lymphocyte count was 4,655/cu mm in group 1 children and 4,907/cu mm in group 2 patients, with five individual values between 1,500 and 2,000/cu mm.

No children had diminished immunoglobulin levels. Increased IgG levels were noted in the serum of seven of ten in group 1 but in only one of four examined in group 2. Levels of IgM were increased in nine of ten in group 1 and in three of five in group 2. Levels of IgA were also increased in nine of ten in group 1 and in only two of five in group 2. These findings suggest an increased humoral immune stimulation in patients in group 1 compared with those in group 2.

Infectious Illnesses

Culture-documented clinical infections and presumed bacterial or fungal infections are given in Table 2. In group 1, those with noticeably abnormal E rosette values, 19 clinical infections occurred in 11 patients; none was free from evident infection. Eight patients in this group had clinical infections at the time of their hospital admission; clinical infections developed in three while they were hospitalized. This included a 2-month-old boy with a staphylococcal pseudomembrane in the posterior pharynx and possible sepsis in whom granulocytopenia developed shortly after admission and he did not respond to antibiotic therapy. Improvement in his clinical status was temporally related to placement of a central alimentation line and granulocyte transfusion. The granulocytopenia resolved spontaneously and did not recur.

An *Escherichia coli* urinary tract infection and *Enterobacter cloacae* septicemia occurred in a 2½-month-old boy with chronic diarrhea five days after admission. His condition improved with antibiotic therapy and adequate nutrition via a central line.

A 4-month-old boy had four episodes of sepsis during a lengthy hospitalization. This child had GI malabsorption that did not improve with multiple different feeding regimens. The patient had been hospitalized for 3½ months, had had three episodes of sepsis, but still had not had substantial weight gain at the time of this evaluation. Only after a central alimentation line was placed for total parenteral nutrition did weight gain occur and septic episodes cease. He had a history of recurrent hematest-positive stools with oral feedings. This could indicate increased gut permeability and susceptibility to infection that also would have improved with the no oral feeding regimen.

Only one patient in group 1 had considerable problems with infections after nutritional replacement. This patient was a malnourished 13½-year-old girl with cystic fibrosis who had been hospitalized every two months for increased pulmonary infection during the preceding ten-month period. With the placement of the central feeding catheter and doubling of her daily caloric intake, she gained weight and was not hospitalized again for 12 months. Her central feeding catheter was also used for intravenous antibiotic therapy that certainly could have contributed to her year-long clinical improvement. She subsequently died of pneumonia, presumably due to an influenza A viral infection.

Of the patients with slightly depressed or normal cellular immunity (group 2), only one had a clinical infection, a *Candida* diaper rash. None of the others in this group had an infectious illness on admission nor did clinical infection subsequently develop during hospitalization. When those patients who had placement of a central venous line were examined separately, none had episodes of sepsis or local infection that could be related to the IV catheter.

Nutritional Studies

Five of 21 children tested had a low serum albumin level and six of 21 had low total protein levels. Seven of 23 had low hemoglobin levels, nine of 14 had low serum iron levels, and six of 12 had low transferrin levels. Mean values for albumin, total protein, and hemoglobin levels were not low in either group 1 or 2. Mean serum iron and transferrin values were low in the whole study population but without a significant difference between groups 1 and 2.

COMMENT

Our findings document the presence of severe and moderately severe malnutrition in a hospitalized pediatric population, although the actual extent of malnutrition was not determined in this study. In a survey of a general adult medical ward,[15] 54% of the patients had moderate to severe mal-

nutrition based on clinical and anthropometric evaluation. A similar study would be appropriate in a pediatric facility.

The at-risk pediatric population for malnutrition in this study seemed to be a group of younger chronically ill children, with long-standing disease, as evidenced by half of the patients being younger than 1 year of age and less than 90% height/age. This younger-aged population also seems to be at higher risk for serious infections in association with malnutrition, since all episodes of septicemia were observed in these children.

Coexistence of severe malnutrition with an increased prevalence of clinical infection has been previously noted by many investigators.[1,2] The use of E rosettes as a sensitive indicator of depressed CMI in pediatric patients has been reported by Ferguson et al[5] and a decreased percentage of E rosettes was associated with an increased incidence of clinical infections in their study of Ghanian children. In this present study, as in the study by Ferguson et al, the decreased percent of E rosettes did not always correlate with severity of infection but only with the presence of some type of infectious illness. Anthropomorphic measurements and biochemical and hematologic abnormalities associated with malnutrition did not correlate with the presence of clinical infection and low rosette valnor did they in previous investigations.

In this patient population, the percentage of E rosettes was decreased and the absolute number of lymphocytes was decreased. It is difficult to determine whether the decreased T-lymphocyte values were the result of infections or were evidence of increased susceptibility to infectious illness because most patients had both when their conditions were initially evaluated. However, serious bacterial infections subsequently developed in three patients with no evidence of clinical infection and low rosette values when first seen. One might speculate that the infections occurred in these patients because of lack of T cells, as they have a role in antigen processing for specific immunoglobulin production. This does not rule out the presence of other immune defects in severe malnutrition (ie, in the complement system and phagocytic cells) that would also contribute to increased infection. However, these aspects of immunity were not examined in this patient group. Since there is known depression of cellular immunity after many viral infections, it would have been helpful to confirm the presence or absence of a preceding viral infection in these patients. Unfortunately, this possibility was not considered at the time.

Values for PHA, although decreased in nine (41%) of the patients examined, were not different in the two groups. Indices of PHA stimulation have been reported to be decreased in severely malnourished patients, although not consistently. The presence of this abnormal finding in slightly less than half of our patients may reflect small sample size. It may also indicate that PHA indices are not as sensitive an indicator of depressed cell-mediated immunity in pediatric patients as are E rosettes. The PHA indices did not correlate with the presence of clinical infection in this population.

The elevated immunoglobulin levels, particularly IgA and IgM in group 1 patients may reflect response to infection in some patients or a loss of some suppressor control of immunoglobulin synthesis associated with decreased cellular immunity. Absolute lymphopenia occurred in 21% of our patients; Ferguson et al[5] had reported 5% and Smythe and associates[3] reported 27% in their pediatric patients with severe malnutrition. Lymphopenia did not correlate with depressed E rosettes or with presence of clinical infection.

The association of decreased E rosette levels with malnutrition and infection does not seem to occur in malnourished adult hospitalized patients. Bistrian et al[9,10] reported hospitalized adults with marasmus and PCM who had normal in vitro tests of CMI, including absolute lymphocyte counts, E rosettes, and lymphocyte transformation to PHA, concanavalin, and other mitogens and antigens. Law et al[8] showed a depressed response to PHA and pokeweed mitogen in malnourished adults as compared with controls, but they did not evaluate E rosettes.

We consider the depression of E rosette levels as one possible indicator of increased susceptibility to clinical infection in malnourished children. This should be examined further by studying a larger group of malnourished hospitalized pediatric patients, and correlating both E rosettes and delayed hypersensitivity skin-test responses with prevalence of infections. Other variables of the immune system, ie, complement system and phagocytosis, need to be evaluated in this population as well.

'Normal' Technetium Bone Scans in Patients With Acute Osteomyelitis

Ivor D. Berkowitz, MB, BCh, Wayne Wenzel, MD

• **Several investigators have stressed the usefulness of the technetium bone scan in the early diagnosis of acute osteomyelitis. Seven patients with acute osteomyelitis had initial bone scans that were reportedly normal. The diagnosis was made as a result of either an abnormal gallium scan, positive cultures, or changes in follow-up roentgenograms. The explanation for the normal technetium scans is conjectural but may be related to compromised vascularity. A normal scan does not rule out acute osteomyelitis. If this diagnosis is strongly suspected, other diagnostic tests should be used.**

***(Am J Dis Child* 134:828-830, 1980)**

Numerous reports in recent years have emphasized the usefulness of technetium bone scintigraphy in the early diagnosis and localization of acute osteomyelitis, as well as the disease's differentiation from cellulitis, bone infarction, and septic arthritis.[1-5] Some authors have even expressed the opinion that a normal scan rules out acute osteomyelitis.[2-4] This report, which describes the occurrence of falsely normal technetium scans in patients with acute osteomyelitis, is prompted by our recent experience in managing several patients with this disease in whom normal bone scans were reported.

SUBJECTS AND METHODS

The patients described were hospitalized at either the Children's Hospital of Denver, the University of Colorado Medical Center, Denver, or Denver General Hospital during the years 1975 to 1979. Roentgenograms and technetium bone scans were performed within 48 hours of admission because of the clinical suspicion of acute osteomyelitis. Gallium scans of some patients were obtained later in the hospitalization because of persistent symptoms and signs consistent with the diagnosis of acute osteomyelitis in spite of reportedly normal roentgenograms and technetium bone scans. Repeated roentgenograms of most patients were obtained eight to 16 days after the onset of symptoms. The technetium Tc 99m medronate (Methylene Diphosphonate [Sn] Kit) and gallium citrate Ga 67 scans were performed using standard methods and doses. Localized vascular-flow studies were routinely done on patients examined for possible osteomyelitis. Multiple angle scintigrams were performed after a two-hour delay using a standard 37-tube Anger camera or a linear multiplane emission computerized tomographic unit. Gallium scan images were obtained in the same manner after a 48-hour delay using the same equipment. Criteria for the diagnosis of acute osteomyelitis included a consistent clinical presentation together with either (*a*) focal uptake of gallium citrate Ga 67 by the affected bone; (*b*) subsequent roentgenographic evidence of bone destruction or periosteal reaction; or (*c*) aspiration of pus from affected bone.

RESULTS

The cases of seven patients with acute osteomyelitis are described. A summary of the patients' ages, the sites of lesions, and the roentgenographic, scintigraphic, and microbiologic findings is given in the Table. The ages of the patients ranged from 3 weeks to 8 years. The technetium Tc 99m medronate bone scan in each of the cases was reported as showing no focal uptake by bone (Figure). The technetium scans were performed three to five days, and the gallium scans seven to eight days, after the onset of symptoms. The diagnosis of acute osteomyelitis was confirmed by subsequent roentgenographic changes in four patients, by an abnormal gallium scan and positive culture in one patient, and by an abnormal gallium

scan alone in two patients. Repeated technetium scans were not performed. All patients recovered with appropriate antibiotic management.

COMMENT

In spite of the reports emphasizing the usefulness and sensitivity of technetium Tc 99m medronate bone scintigraphy in confirming the diagnosis of acute osteomyelitis as early as 24 to 48 hours after the onset of clinical symptoms,[2,3] the cases herein reported demonstrate that the disease can be present despite a normal or equivocally abnormal bone scan. With the exception of the case reported by Garnett et al[6] and rare mention of a falsely normal scan in some series,[2,3] this phenomenon has not been, to our knowledge, previously emphasized.

An explanation for this finding is conjectural. Evidence suggests that the accumulation of technetium Tc 99m medronate by bone is dependent on ionic exchange, the phosphate moiety of the technetium phosphate complex exchanging with phosphate on the hydroxyapatite crystal surface. This exchange will occur at an

Left, Normal technetium Tc 99m medronate scan, case 4. Right, Roentgenogram 18 days after onset of symptoms, showing osteolytic lesions in second right metatarsal, case 4.

increased rate in all areas of accelerated bone turnover whether this increased activity is normal, eg, epiphyseal centers in children, or pathologic, eg, osteomyelitis or fractures.[4-7] This localization of isotope is also facilitated by the increase in bone vascularity that frequently accompanies bone infection.

The vascular factors involved in pathogenesis of acute osteomyelitis have been reviewed by Waldvogel et al.[8] Infection within the metaphysis with intraosseous pus accumulation, sinusoidal thrombosis, venous thrombophlebitis, and possible subperiosteal abscess compression of the nutrient arteries can produce areas of metaphyseal ischemia. The net effect of focal ischemia, offset by the increased extraction of radionuclide associated with osteoblastic proliferation, may explain the occasional normal bone scan. There are, in fact, reports of cases of acute osteomyelitis in which "cold" lesions on bone scan have provided scintigraphic evidence of focal bone ischemia.[3,9,10]

Five of our patients with normal or equivocally abnormal technetium scans subsequently had abnormal gallium scans. The reason for this is unclear but may be explained by the different mechanisms of technetium Tc 99m medronate and gallium citrate Ga 67 concentration in inflamed tissues. The increased gallium citrate Ga 67 uptake is due to the accumulation of in vivo labeled leukocytes, especially polymorphonuclear leukocytes, as well as to the exudation of various in vivo labeled serum proteins. This uptake is not dependent on blood flow and would not be expected to be decreased around areas of ischemia if these were associated with acute inflammation. Although subsequent technetium scans were not obtained, it is possible that these may have been abnormal because of increased osteoblastic activity associated with bone repair. Since the technetium and gallium scans were not performed on the same day, no comparison can be made in this study as to their relative sensitivity in the early detection of acute osteomyelitis. This information is not, to our knowledge, available from the literature.

Lisbona and Rosenthall[11] have suggested that in some cases sequential technetium 99m Tc medronate and gallium citrate Ga 67 scans may help in the diagnosis of acute osteomyelitis. Subtle lesions close to the growth plates were sometimes better seen with gallium scans.

This study was retrospective, and since not every case reviewed has had a technetium scan performed as part of the diagnostic workup, the frequency of falsely normal results for this procedure could not be accurately determined. Forty-nine patients were identified by discharge diagnosis as having acute osteomyelitis; 31 of these had had technetium Tc 99m medronate scans performed, of whom seven were selected for the reported cases.

The purpose of this study is to introduce a note of caution into the report of a normal technetium bone scan in the patient with suspected acute osteomyelitis. A normal bone scan does not rule out this diagnosis. If clinical suspicion is strong, then other steps to confirm the diagnosis, eg, a gallium scan or needle aspiration of the bone, should be performed and appropriate antibiotic therapy begun.

Staphylococcus aureus Sepsis in Childhood Malignancy

James S. Miser, MD, Angela W. Miser, MB, BS

• **Forty-five episodes of *Staphylococcus aureus* septicemia occurred in 44 children with malignant neoplasms over a seven-year period. The most frequent findings at diagnosis were fever, neutropenia, and an active malignant process. Twenty-six (58%) of 45 episodes had a primary focus of infection. Multiple-organism sepsis occurred four times; three episodes were fatal. Only one patient with single-organism *S aureus* sepsis died (a mortality of 2%). Direct infectious complications occurred in nine (20%) of 45 episodes. Endocarditis and osteomyelitis were not seen as complications of *S aureus* sepsis.**

(*Am J Dis Child* 134:831-833, 1980)

Staphylococcus aureus is a common cause of infections and bacteremia in children and adults[1,2] though not the most common pathogen in infections acquired by hospitalized patients.[1-6] Although children with cancer have a high incidence of *S aureus* infections,[7] the mortality is low.[8] This differs from the high mortality of *S aureus* sepsis associated with acute endocarditis seen in heroin addicts[9,10] and in patients without a primary site of infection.[2] Recent studies suggest that patients who have a primary site of infection[2] or a removable focus of infection[11] almost never have bacterial endocarditis. As in a previous study,[8] bacterial endocarditis was not seen in our patient. Our study confirms and extends the observation that the mortality due to *S aureus* sepsis in children with cancer is low[8] but reports a notable (20%) infectious-complication rate.

METHODS

The medical records of all oncology patients at the Children's Orthopedic Hospital and Medical Center, Seattle, from January 1972 to July 1977, and the medical records of all oncology patients at Columbus (Ohio) Children's Hospital from January 1978 to July 1979 who had a documented episode of *S aureus* sepsis were reviewed.

Established criteria were used to assess the clinical significance of staphylococcal isolates from blood.[12] All cases were examined for localized foci of staphylococcal infection. If a lesion was found at initial presentation, it was classified as a primary focus of staphylococcal infection that led to bacteremia. If the lesion developed after the first hospital day, it was arbitrarily defined as a secondary focus.

Blood cultures were obtained by inoculating venous blood directly into bottles containing Trypticase soy broth under partial vacuum. *Staphylococcus aureus* was identified using routine bacteriologic methods. Susceptibility of isolates to antibiotics was determined by a single-disk diffusion method.[13]

The complete blood cell count was obtained using an automatic cell counter,[14] and the absolute neutrophil count was determined by multiplying the percentage of polymorphonuclear leukocytes in the differential cell count by the leukocyte count.

The following information was found: primary site of infection, sensitivity of the organism to penicillin, response to therapy, and secondary staphylococcal infectious complications during or following therapy.

RESULTS

Patient Population

Forty-five episodes of staphylococcal sepsis occurred in 44 patients (27 boys, 17 girls). Thirty-six episodes occurred in patients with hematologic malignant neoplasms (leukemia or lymphoma), whereas nine occurred in patients with a malignant solid tumor (Table 1). Unlike a previous study,[8] this distribution did not reflect the distribution of these diagnoses in the total patient population.

Thirty-four (76%) of the children were in relapse of the malignancy and 31 (69%) were neutropenic (absolute neutrophil count, < 500/cu cm). Four of the 11 episodes in remission occurred in patients who had previous-

ly undergone allogeneic bone marrow transplantation.

The Organism and the Infection

Forty-four of the 45 isolates were tested for antibiotic sensitivity; 36 (82%) were resistant to penicillin. Single-organism sepsis occurred in 41 (91%) of 45 episodes. *Staphylococcus aureus* sepsis was complicated by *Candida* organisms in two episodes and by *Escherichia coli* in the remaining two episodes.
